Triglycerides present a more difficult analytical challenge, since they comprise a heterogeneous population of acylglycerol species. The Centers for Disease Control recognize a reference method for triglycerides, based on extraction, alkaline hydrolysis to generate glycerol, and oxidation of glycerol to formaldehyde; formaldehyde reacts with chromotropic acid to form a colored adduct.[24] As with cholesterol, a GC/MS procedure may eventually supersede the wet chemical method. A recent example of a GC/MS method[25] involves extraction of triglycerides into a chloroform–methanol solvent, followed by solid-phase extraction. Specimens were hydrolyzed with ethanolic potassium hydroxide at 70 °C for 2 h, and isotopically labeled tripalmitin was used as the internal standard for calibration and quantitation. *N*-Methyl-*N*-trimethylsilyltrifluoroacetamide was used to generate the TMS derivative of glycerol before GC/MS analysis. The identity of the derivative was verified by negative ion/chemical ionization MS, which produced a protonated molecular ion. For triglyceride standards, the GC/MS method produced results that deviated less that 0.3% from expected values.

4.2.4 Therapeutic and Abused Drugs

GC/MS confirmation of positive screening results for abused drugs is commonplace, whereas immunochemical measurements of therapeutic drugs are rarely confirmed. There are, however, GC/MS applications for less commonly abused drugs and therapeutic agents for which immunochemical methods are not available. Three examples will be considered here: lysergic acid diethylamide (LSD), busulfan, and mannitol/sorbitol.

LSD is a semisynthetic hallucinogenic drug that is derived from ergot alkaloids. Detection and measurement of LSD is difficult because of the potency of the drug; a typical dose may be between 40 and 120 μg, and the parent compound is extensively metabolized.[26,27] A method has been described for GC/MS measurement of *iso*-LSD,[28] which is a co-product in the hydrolysis reaction that produces LSD from isomeric ergot precursors. Prior to analysis, *iso*-LSD was extracted into 1-chlorobutane after alkalization, and the *iso*-LSD was converted to LSD by a hydrolytic isomerization reaction using sodium ethoxide. The product was purified by solid-phase extraction, then liquid–liquid extraction prior to derivatization with BSTFA. GC/MS analysis included separation on a 5% phenylmethyl siloxane capillary column, and electron impact ionization. Quantitation of *iso*-LSD was based on a nonisotopic internal standard, lysergic acid methylpropylamide, and the method was capable of detecting *iso*-LSD at a concentration of 50 ng per liter of urine.

Busulfan (1,4-butanediol dimethanesulfonate) is a chemotherapeutic agent that is used for marrow ablation prior to bone marrow transplant, but in high doses it can be toxic to the liver and central nervous system.[29] These adverse effects are relatively common, and frequently fatal.[30] In an effort to correlate plasma concentrations of busulfan with clinical outcomes, a GC/MS method was developed for measuring busulfan in the plasma of patients being prepared for bone marrow transplant.[31] Pusulfan (1,5-pentanediol dimethanesulfonate) was added to the plasma specimens as internal standard before extracting the drugs into ethyl acetate. Busulfan and pusulfan were iodinated prior to GC/MS analysis. The chromatographic separation was on a nonpolar capillary column (methyl silicon), and electron impact ionization was used for mass spectral analysis. Quantitative analysis of busulfan had a between-day imprecision of approximately 8%, and the limit of detection corresponded to 2 μg per liter of plasma.

Mannitol and sorbitol are often added to irrigation fluids used in endoscopic procedures to adjust their osmolality.[32,33] Absorption of these compounds can lead to complications, so it may be important to monitor mannitol and sorbitol concentrations in patients undergoing certain endoscopic procedures.[34] A method has been described[35] for GC/MS measurement of mannitol and sorbitol using dulcitol as internal standard. Specimens were deproteinized with ethanol, and the *n*-butyldiboronate derivatives were generated by reaction with *n*-butyl boronic acid. Chromatographic separation

was sufficient to resolve mannitol and sorbitol peaks from several potentially interfering compounds, including D-galactose, D-arabinose, D-ribose, and D-xylose. The mass spectrometer was set for electron impact ionization, and identification of mannitol and sorbitol derivatives was based on the fragment $m/z = 253$.

4.2.5 Fatty Acids

Fatty acids are important components of metabolic reactions, and concentrations in biological specimens can be affected by the presence of metabolic disorders or dietary deficiencies. The general structure of fatty acids is R−COOH, where R is an alkyl chain. Because fatty acid structures are analogous, measurement of individual compounds in this group by chemical analysis is difficult without first separating the different fatty acids. GC/MS is well suited to fatty acid analysis, because it involves both separation and specific detection based on the mass of the analyte.

Oxidation of fatty acids occurs in the mitochondria, and the ultimate product of fatty acid catabolism is acetyl-coenzyme A (CoA), which enters the Krebs cycle. Fatty acid β-oxidation is an important source of energy when dietary sources are unavailable or insufficient to meet physiological demands. There are several genetic disorders that result in compromised to nonexistent mitochondrial β-oxidative capacity, and these disorders often go unnoticed at birth since fatty acid utilization is negligible except under circumstances of dietary restriction or unusual energy expenditure.[36] Measurement of fatty acids in plasma or urine can help reveal metabolic deficiencies in the oxidation of these compounds.

In one recently described method,[37] C-6 through C-18 fatty acids were measured by a GC/MS procedure in plasma obtained from patients with various mitochondrial fatty acid β-oxidation defects. Hydroxylated fatty acid analogs (3-hydroxyhexanoic acid and 3-hydroxyoctanoic acid) were used as internal standards. Plasma specimens were acidified before extracting the fatty acids into ethyl acetate. The reactive carboxylic acid ends of the analytes, and free hydroxy groups of the internal standards, were derivatized with *N*-(*tert*-butyldimethylsilyl)-*N*-methyltrifluoroacetamide (MTBSTFA) and *N*-methylbis(trifluoroacetamide) (MBTFA) in pyridine, and the mass spectra were generated with electron impact ionization. This method was a modified version of a previously described procedure involving bis-trimethyl derivatives.[38]

In another procedure,[39] C-12 through C-22 fatty acids were measured in plasma from patients with three types of disorders: medium-chain acyl-CoA dehydrogenase deficiency; very long-chain acyl-CoA dehydrogenase deficiency; and mild-type multiple acyl-CoA dehydrogenase deficiency. Nonanoic and nonadecanoic acids were used as internal standards. The fatty acids were methylated[40] and extracted into hexane prior to GC/MS analysis on a nonpolar column with electron impact ionization.

A method has also been described[41] for GC/MS measurement of fatty acid ethyl esters in order to quantify the activity fatty acid ethyl ester synthase, which is thought to be released in alcoholic liver and pancreatic disease.[42] Although enzymes can be measured directly, most assays quantify enzyme activity by measuring the rate at which substrate is consumed or product is generated. Enzymes are important biological markers, because their release into the blood can be a sensitive indicator of tissue damage. Ethanol abuse is common in western societies, but the mechanisms by which it causes organ damage are not well understood. Fatty acid ethyl ester synthase activity was quantified by measuring its product by GC/MS. Ethanol and palmitic, stearic, oleic, and arachidonic acids were added to serum specimens and incubated for 4 h at 37 °C. Following incubation, the fatty acid ethyl esters were extracted into a chloroform–methanol phase, and ethyl heptadecanoic acid was added as internal standard. Fatty acid esters were purified by thin-layer chromatography before GC/MS analysis.

4.2.6 Urinary Organic Acids

There are numerous enzymes involved in metabolic pathways using amino acids to synthesize compounds of biological importance, and genetic deficiencies in these enzymes result in the accumulation, and excretion, of large amounts of the precursor compounds. Collectively, many of these inherited disorders are known as organic acidurias, since the appearance of abnormal concentrations of organic acids in the urine is used to detect the disease. GC/MS is an attractive technique for urinary organic acid profiling, owing to its resolution, specificity, and sensitivity. Several methods for measuring urinary organic acids have been described; a few of these are summarized in Table 4.

Methylmalonic aciduria can result from inhereted methylmalonyl-CoA mutase deficiency or defects in cobalamin (vitamin B_{12}) metabolism.[43] Vitamin B_{12} can be measured in patients with suspected genetic defects in cobalamin metabolism, but the test is not specific.[44] Measurement of methylmalonic acid in blood or urine is a more sensitive test for disorders associated with vitamin B_{12} metabolism. A method has been described for measurement of methylmalonic acid in urine collected and dried on filter paper.[45] Measured sections of filter paper were rehydrated, and organic acids were partitioned into ethyl acetate after acidification of the aqueous filter paper extract. TMS derivatives were synthesized

Table 4 GC/MS methods for detecting organic acidurias

Analyte	Derivative	Internal standard	Reference
Methyl-malonic acid	BSTFA/TMCS	Isotopic	McCann et al.[45]
Orotic acid	BSTFA/TMCS	Isotopic	McCann et al.[50]
Profile	Ethoxylamine HCl, BSTFA and perdeuterated BSTFA	External calibration	Shaw et al.[53]
Profile	Hydroxylamine, BSTFA/TMCS	External calibration	Duez et al.[52]

TMCS, trimethylchlorosilane.

prior to GC/MS analysis on a 5% phenylmethylsilicone capillary column and electron impact ionization. Quantitative measurements of urinary constituents can be difficult to interpret since their concentrations can vary depending on the total volume of urine produced. Because the amount of excreted creatinine is relatively constant, its concentration is sometimes used to compensate for variations in total urinary output. In this method for urinary methylmalonic acid, creatinine was measured in the aqueous filter paper extract, and the acid concentration was expressed relative to creatinine concentration. Trideuterated methylmalonic acid was added as internal standard.

Inherited deficiencies in urea cycle enzymes usually result in an accumulation of intermediary compounds. One of these intermediates, orotic acid, is increased in several urea cycle disorders, the most common being ornithine transcarbamylase deficiency.[46] Several methods for chromatographic or GC/MS measurement of orotic acid in urine have been described.[47–49] In a procedure involving collection of dried urine specimens,[50] soluble urine components were eluted from measured sections of filter paper by shaking with 5 mL of water, and creatinine was measured in the eluate for reasons explained above. An isotopically labeled internal standard was added to the extract, and organic acids were extracted into ethyl acetate after acidification. TMS derivatives were synthesized using BSTFA/TMCS, and the analytes were separated on a 5% phenylmethylsilicone capillary column. Mass spectra were obtained by electron impact ionization.

More general approaches to diagnosing inherited metabolic disorders involve methods similar to drug screens, where the intent is to detect multiple constituents and reveal unusual concentrations when they exist. HPLC has been applied to screening urine for inherited metabolic disorders,[51] and more recently GC/MS analysis of volatile derivatives of organic acids in urine has been used for this purpose. The difficulties associated with designing a useful analytical procedure increase in proportion to the number of analytes it is intended to measure, and the challenge of diagnosing inherited metabolic disorders is considerable. A recent paper described a typical approach to quantitative profiling of urinary organic acids.[52] After addition of nonphysiological internal standards (2-ketocaproic and *dl*-tropic acid) urine specimens were incubated with hydroxylamine for 30 min, then acidified with HCl before extracting organic acids into ethyl acetate. The organic acids were further purified by two cycles involving addition of ammonia–ethanol and re-extraction. TMS derivatives were generated using BSTFA/TMCS–pyridine before GC/MS analysis. Twelve organic acids were quantitated by comparison of the ion intensity for characteristic fragments with the internal standards. Coefficients of variation ranged from 2.8% to 20.8% (within-run), and recoveries from standard solutions varied from 78% to 251%; most of the organic acids, however, had acceptable recoveries between 90% and 110%. A few of the organic acids exhibited a nonlinear response, which may explain the highly variable recovery data.

In another urinary organic acid profiling procedure,[53] ethoxime derivatives were synthesized by addition of ethoxylamine HCl prior to acid extraction and derivatization with BSTFA/TMCS. A novel feature of this method was the use of perdeuterated BSTFA in order to identify unknown constituents that appeared in the chromatogram based on the ion shift observed in the characteristic fragment. Using this procedure, the Krebs cycle intermediates, citramalic, tartaric, and 3-oxyglutaric acids, were identified in urine from two patients diagnosed with autism. Arabitol and arabinose were also identified.

4.2.7 Blood Lead

GC/MS is most useful for qualitative and quantitative analysis of organic molecules, but this versatile technique can be applied to nonorganic analytes as well. An example of clinical and toxicological interest is lead. Lead is a potent biological toxin, exposure to which can occur from many sources, such as paints, ceramics, plumbing, and environmental contamination. Lead exposure is particularly damaging in childhood, since it may result in central nervous system toxicity, developmental delays, and learning disabilities.[54] In adults, lead poisoning is manifested primarily in hematological disorders, including anemia, and hypertenstion. Screening of school-age children for lead toxicity has been suggested in order to identify children at risk for lead-related problems.

Lead inhibits the activity of amino levulinic acid hydratase, an enzyme involved in the synthesis of heme from porphyrin, and the accumulation of protoporphyrin

in red blood cells is an indication of lead exposure, although it is less sensitive than direct measurements of lead in whole blood. The most common methods for measuring lead in blood involve electrothermal atomic absorption spectrometry, or electrochemical methods.[55] However, a GC/MS method has been described[56] for measuring lead in blood. A low-abundance isotope of lead (^{204}Pb; natural abundance 1.48%) was used as internal standard, and the method was calibrated against pure and matrix-matched standards. Whole-blood specimens were digested with concentrated nitric acid, and the free lead ions were complexed with ammonium pyrrolidine dithiocarbamate. The lead complexes were extracted into toluene, and 4-fluorophenylmagnesium bromide (Grignard reagent) was added to generate the $Pb(FC_6H_4)_4$ complex. The complex was measured by negative ion/chemical ionization MS using methane as the reagent gas. Typical within-run imprecision for the method was 0.5%, and quantitative results were possible at concentrations as low as 1 μg per liter of blood. The general approach, involving complexation, extraction, and GC/MS analysis with an isotopic internal standard is adaptable to other heavy metals.[57]

5 CLINICAL APPLICATIONS OF MASS SPECTROMETRY

It has been previously noted in this article that mass spectrometric analysis requires pure specimens, and this limitation complicates its application to bioanalyses, where complex matrices are commonplace. There are strategies for overcoming this limitation, however, and these techniques have been applied successfully to detection and quantitation of biomolecules in complicated matrices. One strategy involves the use of high-resolution inlet systems; GC is but one example that was discussed in the previous section. Another analytical strategy involves the use of tandem mass spectrometers, the first stage of which selects a pertinent fragment and the second stage measures daughter ion fragments produced therefrom. Also, mass spectrometric methods designed to measure large molecules using soft, or low-energy, ionization techniques are less affected by impurities in the specimen matrix since large fragments with unique masses are often used for identification and quantitation. The potential of mass spectrometric methods for clinical applications have been stressed by several reviewers,[58] and a few representative examples of this promising technology will be discussed here.

5.1 Screening for Inborn Errors of Metabolism

Like the GC/MS applications reviewed in the previous section, MS alone has been applied to screening for inborn errors of metabolism.[59] These screening methods ordinarily involve detection of accumulated metabolic intermediates that result from deficiencies in enzymes necessary for biosynthesis of essential biochemicals. One versatile profiling technique utilizing MS with electrospray ionization[60] involved spotting blood specimens on a piece of filter paper for stable transport to the laboratory. A disk was cut from the filter paper, which was immersed in a methanol solution containing isotopically labeled standards for 13 organic acids. After cold incubation, the methanolic extract was dried and reconstituted in butanolic HCl and incubated at 65 °C for 20 min. The derivatized extract was washed with hexane and dried prior to preparation for dissolution in the electrospray solvent, consisting of an acetonitrile–water mixture (80 : 20). A triple-quadrupole mass spectrometer was used to sequentially select characteristic masses in the first sector, to allow argon-collisional fragmentation in the middle sector, and to allow daughter ion analysis in the final sector. A computer algorithm was developed to tabulate the mass spectral data, perform quantitative calculations, and flag abnormal results. This method facilitated the detection of a wide array of metabolic disorders, including phenylketonuria (PKU), maple syrup urine disease, and methioninopathies. A significant advantage of quantitative techniques such is this one is a notable increase in the specificity of the procedure – falsely positive results are substantially reduced.

Quantitative methods for urinary constituents are inherently problematic because urine volume varies with such factors as liquid intake and renal function. The variability in concentrations of urinary constituents can be compensated, to some degree, by measuring the ratio of one constituent to another, which is less affected by changes in total urinary output. This approach has been used in mass spectrometric procedures designed to detect PKU. PKU is an inherited deficiency in amino acid metabolism that can result in mental retardation unless dietary restrictions are implemented at a very early age. Because PKU is comparatively common among inborn metabolic errors, although its incidence is still less than 0.01%, newborn urine screening for this disease has been widely adopted. As with any screening test for a rare disease, though, a slight underperformance in specificity results in a large number of falsely positive results, and low predictive value.[61] Falsely positive results of screening tests for heritable diseases can result in unnecessary anxiety and expensive follow-up testing. A recent report[62] describes a mass spectrometric method for detecting PKU. The clinical sensitivity and specificity of the screening test was improved by using the ratio of phenylalanine to tyrosine. Tandem MS (MS/MS) was used to quantify phenylalanine and tyrosine

following initial screening for hyperphenylalaninemia by a fluorometric method. The MS/MS procedure confirmed PKU in less than 2% of specimens classified as positive by fluorometry. Other studies have produced similar results.[63]

MS/MS has been applied to the detection of maple syrup urine disease, a rare disorder that traces its name to the sweet odor of accumulated branched-chain amino acids in the urine. The disease is caused by a deficiency in branched-chain α-keto acid dehydrogenase activity, which is responsible for the oxidative decarboxylation of leucine, isoleucine, and valine. Measurement of blood leucine can reveal maple syrup urine disease at an early age when dietary restrictions are helpful in preventing the severe mental and physical complications that accompany the disease. In the MS/MS procedure,[64] butyl derivatives of amino acids extracted from filter paper blood spots were prepared by reaction with acidic 1-butanol. Deuterated alanine, valine, leucine, methionine, phenylalanine, tyrosine, and glutamine, as well as $[^{15}N_1,^{13}C_1]$glycine, were added as internal standards. The derivatized specimens were reconstituted in a methanol–glycerol solution prior to MS/MS analysis. In the tandem mass spectrometer, a cesium gun was used to vaporize and ionize analyte molecules, and relevant positively charged fragments were selected in the first mass analyzer region. Selected fragments were exposed to argon in the second quadrupole region, and collision-induced decomposition fragments were measured in the third mass analyzer. Predictable neutral-fragment losses in the collision sector yielded high-abundance ions that were used for quantitation. Concentrations of leucine, isoleucine, and valine were expressed relative to phenylalanine concentration. Analytical recoveries of leucine and valine ranged from 86% to 105%, and the method imprecision was less than 11.5% (between-run).

Two inherited metabolic disorders can result in accumulation of methionine in blood: homocystinuria and isolated hypermethioninemia. Homocystinuria results from cystathionine β-synthase deficiency, and hypermethioninemia is most often caused by a deficiency in methionine adenosyltransferase enzyme. Both disorders can result in neurological and skeletal abnormalities. Dietary restrictions, and sometimes pyridoxine supplementation, can improve the prognosis when affected individuals are identified at an early age.[65] An MS/MS technique has been described[66] for measuring methionine in filter paper blood spots, and the method can be used to screen newborns for the associated genetic disorders. In this procedure, amino acids are eluted with a methanol solvent containing deuterated internal standards. The method is substantially the same as the procedure for the branched-chain amino acids leucine, isoleucine, and valine, described above, including derivatization with acidic 1-butanol and use of deuterated internal standards. FAB (cesium ion gun) was used to vaporize and ionize the analytes from a methanol/glycerol solvent. The specimens used to develop this method had been previously screened by a bacterial inhibition assay (Guthrie test). The best precision and correlation with bacterial inhibition results was obtained when quantitative results for methionine quantitation were expressed relative to the sum of leucine and isoleucine concentrations.

Smith–Lemli–Opitz (SLO) syndrome is an autosomal recessive disorder that is characterized by mental retardation, facial dismorphism, and microcephaly, as well as cardiovascular and urogenital malformations.[67] It has been suggested that SLO syndrome results from a deficiency in sterol Δ^7-reductase, which catalyzes the conversion of 7-dehydrocholesterol to cholesterol.[68] As a result, high concentrations of 7-dehydrocholesterol are found in SLO syndrome; the structure of this metabolic intermediate differs from cholesterol only by two hydrogen atoms. A mass-spectrometric method has been described for measuring 7-dehydrocholesterol,[69] using a time-of-flight MS instrument. Neutral sterols were extracted from whole blood into hexane, and applied directly to the MS target platform. An argon beam volatilized the analytes, which were separated in the time-of-flight mass analyzer. Stigmasterol was added as internal standard for quantitation. The method was able to detect 7-dehydrocholesterol in 3 patients diagnosed with SLO syndrome, but not in 10 normal control subjects.

5.2 Protein Measurement

Measurement of proteins involves special analytical challenges, because the chemical composition of proteins consists of only 20 amino acids. Therefore, all proteins have inherently similar chemical compositions. The physical properties of proteins are largely determined by secondary, tertiary, and quaternary structures, which establish the spatial orientation of the primary amino acid chain. Purification techniques that separate components based on size have been used for protein measurement, but these methods are cumbersome and usually imprecise. Certain proteins have unique properties that can be exploited in an analytical method – certain dyes, for example, react with anionic proteins. Most specific proteins are measured by immunochemical methods, but antibody specificity is not absolute, and the chemical similarities between proteins exacerbate the problem of cross-reactivity. For these reasons, reference methods for specific protein quantitation are not widely available, and MS has been proposed as a method to fill that void.

5.2.1 Measurement of Trypsin Cleavage Products

Since measurement of high-molecular-weight species requires specially adapted MS instruments, most approaches to MS protein identification and quantitation involve measurement of smaller protein fragments produced by digestion prior to analysis.[70,71] A general method has been described[72] for quantifying specific proteins by isotope-dilution MS, and a prototype application was designed to measure apolipoprotein A-1 in a standard reference material. In this procedure, the protein is digested with trypsin, which reproducibly cleaves two fragments containing 7 and 11 amino acid residues that are unique to the apolipoprotein A-1 parent molecule. Analogous deuterated oligopeptides were synthesized and used as internal standards. Trypsin hydrolysis was allowed to proceed for 24 h at 37 °C, after which acetic acid was added to quench the reaction. The digestion products were purified by HPLC before measurement on a tandem magnetic sector MS, using FAB ionization (cesium ion gun). The fragments used for MS analysis were characterized by peptide mapping and sequencing by HPLC and nitrogen analysis.

5.2.2 Plasma Renin Activity

Renin is produced in the juxtaglomerular cells in the kidney, and its function is to catalyze the cleavage of angiotensinogen to produce the decapeptide angiotensin 1. Angiotensin-converting enzyme cleaves two amino acid residues from angiotensin 1 to produce angiotensin 2, which is the physiologically active vasopressive form. Angiotensin 2 is rarely measured, because its concentration is very low and it is rapidly degraded into inactive oligopeptides. Therefore, renin activity is customarily assessed by measuring angiotensin 1 concentration. In hypertensive patients, plasma renin activity may help identify whether the cause is renovascular or adrenocortical in origin. Immunoassays have been developed for measuring angiotensin 1,[73] but antibodies may react nonspecifically with other endogenous angiotensins. HPLC has also been used for angiotensin 1 measurement,[74] but most detection systems for HPLC lack the sensitivity to measure clinically relevant angiotensin 1 concentrations.

An electrospray ionization/mass spectrometry (EI/MS) method has been described for measuring plasma renin activity by quantitating angiotensin 1.[75] This method involves incubation of plasma specimens for 18 h at 37 °C to allow the renin-catalyzed conversion of angiotensinogen to angiotensin 1 to occur. A Leu → Val substituted angiotensin 1 analog was used as internal standard; the valine substitution increased the molecular weight by 14 amu. Analytes were extracted from plasma on a solid-phase C_{18} column, and then purified by reverse-phase HPLC. MS analysis was performed on a tandem mass analyzer with electrospray ionizer operating in the positive-ion mode. The limit of detection for the procedure was 0.14 ng of angiotensin 1 per milliliter of blood per hour, and coefficients of variation were less than 15%.

5.2.3 Hemoglobin

Hemoglobin is a tetrameric 64-kDa protein that is the principal oxygen carrier in blood. The hemoglobin tetramer is usually composed of two α-subunits, and two non-α-subunits, which may be pairs of β-, γ-, δ-, or ε-chains. The combinations of paired subunits give rise to several forms of hemoglobin, most of which disappear before or shortly after birth. The predominant form (approximately 96%) of hemoglobin in adults is $\alpha_2\beta_2$, and is designated HbA. Hemoglobins can be post-translationally modified by nonenzymatic covalent addition of sugar molecules at the N-terminal valine residues of the β-chains. The modified form of hemoglobin has been called glycated hemoglobin, and when the sugar is glucose, the complex is designated HbA_{1c}. HbA_{1c} measurement is useful because its formation is regulated by blood glucose concentration, and therefore abnormally high concentrations of HbA_{1c} reflect persistent hyperglycemia.[76] A variety of methods exist for measurement of HbA_{1c}, including affinity chromatography, immunoassay, electrophoresis, and HPLC. There is considerable variation, though, in quantitative HbA_{1c} results obtained by these methods,[77] possibly due to ambiguities in the definition of what HbA_{1c} really is. Unlike chromatographic and immunochemical methods, MS is capable of identifying specific molecular species, and therefore its application to HbA_{1c} measurement and standardization has been suggested.

A proposed candidate reference method for HbA_{1c}[78] involves isolation of red blood cells by centrifugation, followed by lysis in hypotonic solution. Hemolysates were mixed with buffer and cellular debris was removed by centrifugation. Hemoglobin was enzymatically cleaved by endoproteinase Glu-C, generating an N-terminal hexapeptide that was unique to the hemoglobin molecule and contained the sugar residue from glycated hemoglobin species. Endoproteinase cleavage products were separated by HPLC before mass spectral measurement on a single-stage quadrupole instrument with electrospray ionization. The method was calibrated with external standards purified by a combination of cation exchange and affinity chromatographic procedures. Results of the MS method were compared to HPLC measurement of HbA_{1c}, and the two methods produces nearly equivalent results.

A procedure similar to the method described above has been used to detect a genetic hemoglobin variant that is more facile toward glycation.[79] The hemoglobin

Rambam variant, which is characterized by a Gly → Asp substitution at position 69 in the β-subunit, was detected by measuring the mass shift of 58 Da that resulted from the substitution. The single amino acid substitution apparently promotes glycation of β-chain lysine residues, which alters the results of conventional HbA_{1c} measurements.

5.2.4 Albumin

Albumin is the predominant protein in blood, and serves many functions including regulation of plasma osmotic pressure and as a carrier protein for a variety of blood constituents. Numerous genetic variants of albumin have been reported, but interest in these variants is more academic than clinical since they do not ordinarily result in clinical disease. Nevertheless, precise measurement of albumin and its genetic variants is difficult for the reasons described above: its composition is comparable to other proteins, it is not significantly modified post-translationally with unique compounds that might be easily detectable, and genetic variants differ only slightly, often by the substitution of a single amino acid residue. Mass spectrometric analysis of albumin affords the opportunity to resolve the many variants of albumin.

EI/MS has been used to quantify albumin and some of its variants.[80–83] In one procedure,[83] albumin was purified by dialysis and size exclusion gel chromatography on a DEAE–Sephadex column. Eluates were collected and concentrated by filtration and redialyzed. Agarose gel electrophoresis indicated greater than 95% purity of the albumin specimens purified in this manner. Purified specimens were dissolved in the electrospray buffer, consisting of acetonitrile–formic acid (500 : 1) before analysis. The procedure was calibrated with standards prepared from human α-globin and hemoglobin. Using this method, multiple forms of albumin were demonstrated in patients with heterozygous albumin variants. The method was able to resolve mass differences associated with the point mutations 177Cys → Phe (44 Da), 1Asp → Val (20 Da), and Arg-albumin (160 Da), as well as more significant mutations involving carbohydrate and oligosaccharide modifications.

5.3 Drug Measurements

5.3.1 Tacrolimus

MS using non-GC inlet systems has also been applied to drug analyses. One reported example is the use of liquid chromatography and electrospray ionization to detect an immunosuppressive drug, tacrolimus (FK506), in blood.[84] Immunosuppressive therapy has become standard practice in organ transplantation programs, and the availability of potent immunosuppressive agents may be largely responsible for the success these programs have achieved. Immunosuppressive drugs, however, are characterized by a narrow therapeutic index, and the potential for toxicity from these drugs is correspondingly high.[85] Therefore, frequent monitoring of blood levels of immunosuppressive drugs is an important component of this type of therapy.[86] Immunochemical methods for tacrolimus are problematic, because of cross-reactivity of the antibody with metabolites of the drug, many of which may be inactive.[87] Therefore, quantitative results of immunoassays can give misleading results when the concentrations of inactive metabolites are high. HPLC methods can overcome this limitation, but may involve complicated and lengthy specimen preparation procedures.[88] In an MS procedure, blood specimens were mixed with an acetonitrile–water solution to precipitate proteinaceous material. Drugs were purified with a solid-phase extraction column, and reconstituted in the liquid chromatograph mobile phase. Mass spectral analysis was performed on a triple quadrupole instrument with an ion-spray interface to the liquid chromatograph. Collisional dissociation in the middle quadrupole was induced by argon gas. The method was calibrated with a series of external standards.

5.3.2 Anabolic Steroids

Drug-use in athletics has received much attention, and sports drug-testing laboratories have responded with increasingly sophisticated methods for detecting the presence of performance-enhancing drugs. Anabolic steroids are particularly difficult to detect, since many of the abused compounds are endogenous. Metabolic modification of steroid compounds also complicates efforts to detect illicit use. Finally, detection of many anabolic agents requires highly sensitive analytical methods.[89] Ion trap mass spectrometers have the ability to sequester individual fragments, and coupling an ion trap to a conventional quadrupole mass analyzer allows measurements that are both highly selective and very sensitive. The ion trap MS approach has been applied to workplace drug testing,[90] and to measuring anabolic agents in urine.[91] Common features of these applications include solid-phase extraction to isolate the drugs from urine matrix and addition of β-glucuronidase enzyme to hydrolyze glucruonyl conjugates. The drugs were derivatized with BSTFA before injection in the ion trap mass spectrometer.

5.3.3 β-Blockers

Along with anabolic steroids, another class of drugs that has been banned by the International Olympic Committee and International Sports Federation is β-blockers,

which have β-adrenoceptor antagonistic activity. A combined liquid chromatography/electrospray mass spectrometric method has been described for measuring several of the commonly used β-blocking drugs.[92] The drugs were extracted from serum or urine with a solid-phase C_{18} column prior to liquid chromatography. The mass spectrometer was interfaced to the liquid chromatograph with an electrospray ionizer, and selected ion monitoring was used to measure fragments unique to the β-blocker drugs and their metabolites.

5.4 Elemental Analytes

Because of the high temperatures required to volatilize metallic elements, spectrometric methods for these species typically involve flame or electrothermal atomization. Higher temperatures can be achieved using inductively coupled plasma as the ion source, and MS has been used as a detector for this type of instrument. Urinary iodine,[93] and titanium in spleen tissue[94] have been measured using inductively coupled plasma mass spectrometry (ICPMS).

Iodine is an essential element that is incorporated into thyroid hormones. Iodine deficiency is a well-described clinical condition that is prevalent in many underdeveloped areas of the world.[95] Monitoring urinary iodine is one method for detecting iodine deficiency, and an ICPMS procedure for measuring urinary iodine has been described.[93] Urine specimens were mixed with radioactive ^{129}I as internal standard, and mathematical corrections were made for the conversion of ^{129}I to stable ^{127}I. The accuracy of the method was verified with standard reference materials. An advantage of ICPMS is that minimal sample preparation is necessary, since all organic material in the specimen is destroyed at the 10 000 °C temperature of the plasma discharge.

Another application of ICPMS was developed to detect titanium in spleen tissue, which was suspected to emanate from a titanium-containing articular prosthesis.[94] Paraffin-embedded tissue was removed by heating, then rinsing with organic solvent. Delipidated tissue was digested with hot nitric acid before ICPMS analysis. Although results were mostly qualitative, the ICPMS method confirmed the presence of titanium in tissues, correlating with abnormal histological findings that raised the suspicion.

5.5 Characterization of Protein Epitopes

An epitope is the region of an antigen molecule that is recognized by an antibody and is responsible for the noncovalent interactions that result in the formation of an antigen–antibody complex. Epitopes may comprise a continuous sequence of amino acids in the protein molecule, or may include segments brought in close proximity of each other by the secondary or tertiary protein structure. Knowledge of these specific molecular regions that bond to antibodies is essential for understanding the selectivity of antibody-based analytical methods, and for developing effective synthetic vaccines. X-ray crystallographic data have been used to characterize the antigen–antibody complex and reveal complementary regions, but this technique requires isolation of the complex in crystalline form; this is not always possible. Other approaches utilize chemical modification of candidate epitopes, structural variants, and synthetic peptides to provide indirect information about the nature of the antibody–antigen complex. These methods are time-consuming and costly, and the results can be difficult to interpret. An innovative method has been described[96] that uses MS to identify antigen fragments in the presence and absence of antibody by MALDI.

Alkylated human and hen lysozyme were prepared by incubation with 4-vinylpyridine, guanidine hydrochloride, ethylene diamine tetraacetic acid (EDTA), and dithiothreitol in Tris buffer at 37 °C overnight. The alkylated proteins were purified by HPLC, and then digested with endoproteinase for 15 h at 37 °C. The mixture of proteolytic products was incubated with anti-lysozyme IgG for 2 h at 4 °C, and a portion of the resulting solution was prepared for MALDI/MS analysis. A control digest, without antibody, was processed in parallel. The MALDI matrix consisted of α-cyano-4-hydroxycinnamic acid in acetonitrile and water. Mass spectral analysis was performed in the positive-ion mode with a time-of-flight mass analyzer.

The key to epitope mapping by this approach is comparison of antibody-incubated antigen fragments with control fragments in the absence of antibody. Since MALDI is a soft ionization technique, antibody-bound fragments are less susceptible to vaporization. Antigen fragments that appear in control analyses but are absent in antibody-incubated preparations are presumed to be bound to antibody. Mass analysis provides molecular-weight resolution sufficient to identify the peptides bound to the antibody. In the reported experiment, a 13-residue fragment was identified as containing the epitope. Epitope mapping by MALDI/MS is a promising technique that offers the advantages of simplicity, economy and speed.

5.6 Detection of Genetic Mutations

Although both proteins and DNA are polymeric biomolecules constructed from a few available subunits, analysis of DNA material is much more difficult because the phosphodiester-linked strands are less stable than

polypeptides and are prone to the formation of nonvolatile salts. In addition, the amount of DNA available for analysis is usually very small, although amplification techniques can be used to generate sufficient material for analytical studies. DNA analysis has revolutionized several areas of clinical laboratory science, including microbiology, histology, and genetic screening. Most methods for DNA analysis involve hybridization with radioactive, fluorescent, or enzyme-labeled complementary strands.[97] MS has been applied to identification and measurement of DNA probes, using low-energy ionization methods and mass determinations to unambiguously identify relevant oligonucleotides.[98,99]

Cystic fibrosis is an autosomal recessive genetic disorder caused by a mutation in a gene that has been mapped to chromosome 7. The gene, which codes for a protein called cystic fibrosis transmembrane regulator (CFTR), is over 250-kbp in length, and over 500 specific mutations have been identified that cause disease. This high degree of allelic diversity complicates the task of screening individuals for genetic evidence of disease, since the specific mutations exhibit different ethnic incidences. Whereas testing for one group of mutations may identify a high percentage of cystic fibrosis carriers in one population, its sensitivity in another population may be quite low. Analytical methods capable of economically screening for large numbers of mutations would be beneficial. MS is a promising technique for this type of analysis, and methods have been described for detecting mutations associated with cystic fibrosis using MALDI and time-of-flight MS.[100–102]

In one of these procedures,[102] oligonucleotides complementary to several CFTR intron sequences were synthesized and amplified by polymerase chain reaction; the amplification products were purified and used as detection primers. Using a technique called primer oligo base extension (PROBE), primer oligonucleotides were annealed to native DNA, and extension was promoted by polymerase enzyme so that the oligonucleotide was lengthened to include the mutated region. The resulting oligonucleotides were measured by time-of-flight MS, which was able to identify nucleic acid substitutions based on the mass of the fragment produced in the MALDI ionizer. Advantages of this MALDI/MS method are the specificity of oligonucleotide detection, and elimination of the requirement to label probe fragments.

ABBREVIATIONS AND ACRONYMS

BSTFA	*N*,*O*-Bis(trimethylsilyl)trifluoroacetamide
CFTR	Cystic Fibrosis Transmembrane Regulator
CoA	Coenzyme A
EDTA	Ethylene Diamine Tetraacetic Acid
EI/MS	Electrospray Ionization/Mass Spectrometry
FAB	Fast Atom Bombardment
FID	Flame Ionization Detector
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
ICPMS	Inductively Coupled Plasma Mass Spectrometry
LSD	Lysergic Acid Diethylamide
MALDI	Matrix-assisted Laser Desorption/Ionization
MBTFA	*N*-Methylbis(trifluoroacetamide)
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
MTBSTFA	*N*-(*tert*-Butyldimethylsilyl)-*N*-methyltrifluoroacetamide
PKU	Phenylketonuria
SLO	Smith–Lemli–Opitz
TMCS	Trimethylchlorosilane
TMS	Trimethylsilyl

Because of the pivotal role of glucose in physiological processes, much effort has been devoted to the development of methods for measuring glucose in food, microbiological and clinical matrices. The development of direct methods to measure glucose has been hindered by the lack of a suitable chromophore or indeed an electrophore. Consequently, more complex indirect methods have been developed based either on the chemical reactivity of the sugar, a particular enzymatic reaction or an indirect electrochemical measurement based upon the measurement of tensametric peaks or waves.

Although accurate and offering good sensitivity, chemical methods for the analysis of glucose such as the o*-toluidine approach are not specific for glucose. Other hexoses such as mannose and galactose, some of their derivatives, aldopentoses and some disaccharides may also react, thereby complicating the measurement.*

Because of the lack of specificity associated with chemical methods of measuring glucose, enzymatic methods have gained in popularity. Enzymes are very selective biological catalysts which carry out the conversion of a particular substrate into a product under mild operating conditions, i.e. room temperature, low ionic strength and near neutral pH. An enzyme will usually catalyze a single chemical reaction or a set of closely related chemical reactions. Side reactions leading to wasteful formation of by-products rarely occur. Thus, quantitative assays may be done on crude materials with little or no sample preparation. The enzymes which are currently used for the measurement of glucose include hexokinase (EC 2.7.1.1; adenosine triphosphate (ATP): D-hexose-6-phosphotransferase), glucose oxidase (EC 1.1.3.4; β-D-glucose: oxygen 1-oxidoreductase) and glucose dehydrogenase (EC 1.1.1.47; β-D-glucose: (nicotinamide adenine dinucleotide phosphate (oxidized form)) NAD(P)$^+$ 1-oxidoreductase). The mode of detection that is used to measure the activity and hence concentration of glucose, ultimately depends upon the nature of the enzymatic reaction itself and is usually colorimetric or electrochemical.

More recently, new analytical methodologies based upon the direct electrochemical detection of glucose using pulsed amperometric detection (PAD) have been developed. Coupled with liquid chromatography (LC), this technique is proving to be a highly selective and sensitive method for the measurement of glucose in a wide variety of sample matrices.

1 INTRODUCTION

In the leaf of a plant, the simple compounds carbon dioxide and water are condensed to form the monosaccharide sugar (+)-*glucose*. This process, known as photosynthesis, requires the catalytic action of the green pigment chlorophyll and requires energy in the form of sunlight. Thousands of (+)-glucose molecules can then be combined to form polymers such as cellulose, which constitutes the supporting framework of the plant, and starch which is stored in the seeds to form a food reserve for the growing plant.

When eaten by an animal, the starch (and in the case of ruminants the cellulose) is broken down once more into (+)-glucose. The sugar is then carried by the bloodstream to tissue where it is ultimately oxidized to carbon dioxide and water with the concomitant release of energy originally supplied by sunlight. Some of the glucose is converted into fats, some reacts with nitrogenous compounds to form amino acids and some in turn is converted into the storage polysaccharide glycogen.

1.1 Definition and Classification

Glucose belongs to the class of organic compounds known as carbohydrates. Carbohydrates are polyhydroxy aldehydes, polyhydroxy ketones or compounds that can be hydrolyzed to them. A carbohydrate such as glucose

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

that cannot be hydrolyzed to a simpler compound is known as a monosaccharide.

A monosaccharide may be further classified depending upon the presence of certain chemical groups. If it contains an aldehyde group, it is known as an aldose; if it contains a ketone group, it is known as a ketose. Furthermore, depending upon the number of carbon atoms that it contains, a monosaccharide can be classified as a triose, tetrose, pentose, hexose and so on.

1.2 (+)-Glucose: an Aldohexose

(+)-Glucose has the molecular formula $C_6H_{12}O_6$ as shown by elemental analysis and molecular weight determination. The straight chain structure (Fisher projection) of (+)-glucose is shown as Structure **(1)**. It is a colorless crystalline substance with a sweet taste, though not as sweet as cane sugar. It is readily soluble in water but only sparingly soluble in alcohol. Like other monosaccharides, glucose is optically active and the naturally occurring form is dextro-rotatory (D-(+)-glucose). On the whole, glucose displays the properties of an aldose, i.e. it can be oxidized in four important ways: (1) by Fehling's or Tollens' reagent, (2) by bromine water, (3) by nitric acid and (4) by periodic acid. It does however give a negative Schiff test and does not form a bisulfite addition product.

(1)

1.3 Osazone Formation

Because glucose is an aldose sugar it will react with phenylhydrazine to form phenylhydrazones. If an excess of phenylhydrazine is used, the reaction proceeds further to yield products known as osazones which contain two phenylhydrazine residues per molecule at positions 1 and 2.

1.4 Tautomerism and Mutarotation of Glucose

Glucose exhibits tautomerism of a cyclic type made possible by the fact that the chain of carbon atoms in the molecule is not actually straight but is in fact bent around the periphery of a ring. Consequently, the −CHO group is very close to the C−OH group at position 5 and reacts forming an intramolecular hemiacetal to give two anomers known as α- and β-D-(+)-glucose, Structures **(2)** and **(3)**, respectively. The two isomers differ by having opposite configurations for the C1-hydroxy.

(2)

α-D-(+)-Glucose

m.p 146°C, [α] = + 112°

(3)

β-D-(+)-Glucose

m.p 150°C, [α] = + 19°

When crystals of D-(+)-glucose, which have been obtained from alcohol or water, of m.p. 146 °C are dissolved in water, the specific rotation gradually drops from an initial +112° to +52.7°. This change in optical rotation on standing at room temperature is referred to as mutarotation and is caused by tautomeric changes in solution in the original α- and β-glucose to an equilibrium mixture which contains 37% of the α form and 63% of the β form.

2 THE IMPORTANCE OF MEASURING GLUCOSE

Because of the pivotal role of glucose in physiological processes, much effort has been devoted to the development of methods for measuring glucose in food, microbiological and clinical matrices. In addition, the accurate estimation of blood glucose levels plays a very important role in the management of diabetes mellitus, a worldwide health problem involving an insulin deficiency that results in an inability to control blood glucose levels. About 2% of the world's population suffer from insulin-dependent diabetes. The long-term complications of diabetes involve vascular problems such as nerve damage, kidney disease, retinal damage and accelerated arteriosclerosis. Finally, increased levels of plasma glucose have been shown to be associated with hyperactivity of the thyroid pituitary or adrenal glands while decreased levels are observed in cases of insulin overdosage, insulin-secreting tumours, myxedema, hypopituitarism, hypoadrenalism and conditions interfering with glucose absorption. Expected values for normal glucose levels in whole blood or plasma are summarized in Table 1.

Table 1 Expected glucose values in healthy adult subjects

Normal values for fasting adults	
Whole blood	50–90 mg dL^{-1} (2.8–5.0 mM)
Serum or plasma	70–105 mg dL^{-1} (3.7–5.8 mM)

The development of direct methods to measure glucose has been hindered by the lack of a suitable chromophore or indeed an electrophore. Consequently, more complex indirect methods have been developed based either on the chemical reactivity of the sugar, a particular enzymatic reaction or an indirect electrochemical measurement based upon the measurement of tensametric peaks or waves. This article will critically review the current methodologies available for the measurement of glucose.

3 MEASUREMENT METHODS FOR GLUCOSE

3.1 Chemical Methods: the *o*-Toluidine Approach

The usage of *o*-toluidine for the detection of glucose has an established history. In 1959, Hultman and coworkers[1] reported the use of *o*-toluidine **(4)** occupational exposure limit (OEL) 9 mg m^{-3}; LD_{50}, 670 mg Kg^{-1} (oral rat) as a reagent for the colorimetric determination of glucose in body fluids. The color reagent, which was essentially *o*-toluidine in glacial acetic acid (6% v/v), was found to be specific for aldose sugars. In 1962, Dubowski[2] repeated this work and extended the study to include an investigation of the spectral characteristics of the reaction, reaction composition, sensitivity, reproducibility, recovery and specificity. Based on his findings, Dubowski[2] concluded that the *o*-toluidine method fulfilled the requirements of a practical analytical assay for body fluid glucose. In the same year, the assay method was modified by adding thiourea to the *o*-toluidine reagent resulting in improved reagent stability and appreciable lowering of the blank reading.

(4)

o-Toluidine is toxic by inhalation, toxic in contact with skin, toxic if swallowed.

The principle of the assay procedure is that in the presence of heat and acid, *o*-toluidine reacts with glucose to form a blue-green colored complex, the intensity of which is directly proportional to the concentration of glucose (Equation 1).

$$o\text{-toluidine} + \text{glucose} \xrightarrow{\text{acid, heat}} \text{colored complex} \quad (1)$$
$$\text{(measured at 620–650 nm)}$$

Table 2 Substances that interfere with the *o*-toluidine determination of glucose. (Adapted from Sigma Technical Bulletin, Procedure 635 with permission)

Substance	Degree of reaction relative to glucose
Galactose	100%
Mannose	100%
Lactose	33%
Glucuronic acid	20%
Xylose	19%
Maltose	5%

Other hexoses such as mannose and galactose, some of their derivatives, aldopentoses and some disaccharides may also react and form a colored complex with *o*-toluidine, see Table 2. These substances are normally present in low concentrations in body fluids of healthy individuals and do not interfere. Because this procedure does not distinguish between glucose and galactose, the test cannot be used for glucose determination from patients suffering from galactosemia or from those undergoing galactose tolerance tests. A kit for the analysis of glucose using the *o*-toluidine reagent can be purchased from Sigma-Aldrich Co. Ltd, product number 635.

3.2 Enzymatic Methods for Measuring Glucose

Because of the lack of specificity associated with chemical methods of measuring glucose, enzymatic methods have gained in popularity. Enzymes are very selective biological catalysts which carry out the conversion of a particular substrate into a product under mild operating conditions, i.e. room temperature, low ionic strength and near neutral pH. An enzyme will usually catalyze a single chemical reaction or a set of closely related chemical reactions. Side reactions leading to wasteful formation of by-products rarely occur. Thus, quantitative assays may be done on crude materials with little or no sample preparation.

Much of the catalytic power of enzymes comes from lowering the activation energy for reaction through stabilization of the transition state when bound to the enzyme. The substrates are bound to a specific region of the enzyme known as the active site. Most enzymes are highly specific in the binding of their substrates and, indeed, the catalytic specificity of an enzyme is dependent at least in part on the specificity of this binding.

For many enzymes, the rate of catalysis (v_0), defined as the number of moles of product formed per second varies with substrate concentration [S] in a manner shown in Figure 1.

At a fixed concentration of enzyme, v_0 is almost linearly proportional to [S] when the concentration is small. At high substrate concentrations, the rate of reaction

Figure 1 Dimensionless plot of the Michaelis–Menten equation.

becomes independent of [S] and reaches a maximum value. The model proposed, which is the simplest one to account for these kinetic properties, is shown in Equation (2).

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P \tag{2}$$

According to this model, an enzyme molecule E combines with substrate to form an ES complex with a rate constant k_1. The ES complex then has two possible fates; it can dissociate back to E and S, with a rate constant k_{-1} or it can proceed in an irreversible manner to form a product P, with a rate constant k_2. Using this model, it is possible to define a rate equation (Michaelis–Menten equation) for an enzyme-catalyzed reaction which states (Equation 3) that

$$v_0 = v_{max}\frac{[S]}{[S] + K_M} \tag{3}$$

where K_M (the Michaelis constant) is defined as $(k_{-1} + k_2)/k_1$ and v_{max} is the product of the total enzyme concentration and k_3. Thus, when $[S] \ll K_M$ the rate of reaction v is defined as Equation (4):

$$v_0 = \frac{v_{max}[S]}{K_M} \tag{4}$$

that is the rate is directly proportional to [S].

The enzymes that are currently used for the measurement of glucose include hexokinase (EC 2.7.1.1; ATP: D-hexose-6-phosphotransferase), glucose oxidase (EC 1.1.3.4; β-D-glucose: oxygen 1-oxidoreductase) and glucose dehydrogenase (EC 1.1.1.47; β-D-glucose: $NAD(P)^+$ 1-oxidoreductase). The mode of detection that is used to measure the activity, and hence concentration of glucose, ultimately depends upon the nature of the enzymatic reaction itself.

3.2.1 Hexokinase Method (Ultraviolet Measurement)

The methodology for the hexokinase method of quantifying glucose is summarized in Equations (5) and (6).

$$\text{glucose} + \text{ATP} \xrightarrow{\text{hexokinase}} \text{glucose-6-phosphate} + \text{ADP} \tag{5}$$

$$\text{glucose-6-phosphate} + NAD^+ \xrightarrow{\text{glucose-6-phosphate dehydrogenase}} \text{6-phosphogluconate} + \text{NADH} \tag{6}$$

Glucose is phosphorylated in the presence of ATP in a reaction catalyzed by hexokinase. Glucose-6-phosphate is then oxidized to 6-phosphogluconate in the presence of NAD^+ (nicotinamide adenine dinucleotide, oxidized form) in a reaction catalyzed by the second enzyme (known as the indicator enzyme) glucose-6-phosphate dehydrogenase (EC 1.1.1.49; glucose-6-phosphate: $NAD(P)^+$ oxidoreductase). During the oxidation, an equimolar amount of NAD^+ is reduced to NADH (nicotinamide adenine dinucleotide, reduced form) which has a chromophore at 340 nm ($\varepsilon = 6200\,M^{-1}\,cm^{-1}$) and can therefore be measured conveniently using a spectrophotometer. The resultant increase in absorbance at 340 nm is directly proportional to the glucose concentration provided that the reaction is allowed to go to completion. (This is an example of an "end-point" assay procedure). Typically, solutions ranging from 0.5–50 μg of glucose per milliliter should give an $A_{340\,nm}$ between 0.03 and 1.6 (data adapted from Sigma Technical Bulletin GHKB-2). Normal procedures should be carried out with regard to sample preparation. Cloudy samples should be either filtered or deproteinized, solutions which are strongly colored should be decolorized and carbonated or fermented samples should be degassed. A typical enzymatic assay solution contains 1.5 mM NAD^+, 1.0 mM ATP, $1\,U\,mL^{-1}$ hexokinase and $1\,U\,mL^{-1}$ glucose-6-phosphate dehydrogenase (where U is a unit of enzyme activity). Using this solution, assay times at room temperature should not exceed 15 min. An assay kit for determining glucose by this method is available from Sigma-Aldrich Co. Ltd, product number 16-100P. It is important to note that hexokinase is not totally specific for glucose. Indeed, it will catalyze the phosphorylation of other hexoses including D-mannose, D-fructose, 2-deoxy-D-glucose and D-glucosamine. This apparent lack of specificity is unimportant in the assay of glucose since the indicator enzyme is specific for glucose-6-phosphate and will not react with either mannose-6-phosphate or

fructose-6-phosphate without the incorporation of phosphoglucose isomerase (EC 5.3.1.9; D-glucose-6-phosphate ketol isomerase).

3.2.2 Hexokinase Method (Colorimetric Measurement)

An interesting modification of the above method makes use of the fact that reduced nicotinamide coenzyme can give rise to a colored product in the presence of 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyltetrazolium chloride (INT) **(5)** and phenazine methosulfate (PMS) **(6)**, which has a chromophore at 520 nm. In this approach, the reduced coenzyme nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) is oxidized back to $NADP^+$ by PMS. The reduced PMSH is then reoxidized by INT resulting in the colored form of the dye INT-Formazan. The sequence of reactions that constitute this assay method is summarized in Equations (7–10).

$$\text{glucose} + \text{ATP} \xrightarrow{\text{hexokinase}} \text{glucose-6-phosphate} + \text{ADP} \quad (7)$$

$$\text{glucose-6-phosphate} + \text{NADP}^+ \xrightarrow{\text{glucose-6-phosphate dehydrogenase}} \text{6-phosphogluconate} + \text{NADPH} \quad (8)$$

$$\text{NADPH} + \text{PMS} \longrightarrow \text{NADP}^+ + \text{PMSH} \quad (9)$$

$$\text{PMSH} + \text{INT} \longrightarrow \text{PMS} + \text{INT-Formazan} \quad (10)$$

(5)

(6)

An assay kit based upon this methodology is available from Sigma-Aldrich Co. Ltd., product number 115-A. The total test time by this method is 5–10 min. The dynamic range of the test is 0.5–300 mg dL^{-1} (0.028–16.7 mol L^{-1}) and so is useful for plasma glucose determinations where the expected values lie in the range 70–105 mg dL^{-1}. Although more sensitive than the ultraviolet (UV) method, this technique is more prone to interference, particularly if any reducing agents are present in the sample.

3.2.3 Glucose Oxidase Method (Colorimetric Measurement)

Glucose oxidase is a glycosylated flavoprotein which catalyzes the oxidation of β-D-glucose by atmospheric oxygen to produce D-gluconolactone, which is rapidly converted to gluconic acid with the production of hydrogen peroxide, Equation (11)

$$\text{glucose} + \text{O}_2 + 2\text{H}_2\text{O} \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + \text{H}_2\text{O}_2 \quad (11)$$

The enzyme shows a very high degree of specificity for β-D-glucose[3,4] although 2-deoxy-D-glucose, D-mannose and D-fructose are also oxidized albeit at a much reduced rate.[5]

In 1956, Keston[6] proposed the simultaneous use of glucose oxidase and peroxidase (EC 1.11.1.7; donor : hydrogen peroxide oxidoreductase) coupled with a chromogenic electron donor (e.g. *o*-dianisidine, *o*-toluidine) for the colorimetric determination of glucose in body fluids. Since then, numerous workers have adapted the original method (e.g. variations in incubation time, temperature, buffer composition and choice of chromogen) and applied it to the determination of glucose in blood, urine and cerebrospinal fluid. The sequence of reactions that constitute this assay method are summarized in Equations (12) and (13).

$$\text{glucose} + \text{O}_2 + 2\text{H}_2\text{O} \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + \text{H}_2\text{O}_2 \quad (12)$$

$$\underset{\text{(colorless)}}{\text{H}_2\text{O}_2 + \textit{o}\text{-dianisidine}} \xrightarrow{\text{peroxidase}} \underset{\text{(brown)}}{\text{oxidized } \textit{o}\text{-dianisidine}} \quad (13)$$

The intensity of the brown color, which is stoichiometrically proportional to the amount of glucose present in the sample, is measured at 425–475 nm.[6] The chemical structure of *o*-dianisidine (3,3′-dimethoxybenzidine) is shown in Structure **(7)**.

(7)

It has been reported in the literature that several substances may interfere with this procedure. Included amongst these are ascorbic acid, catechols, cysteine, glutathione, acetylsalicylic acid, L-dopamine (L-DOPA), mercurial diuretics and tetracycline. All these tend

to depress the glucose value.[7–14] The presence of exogenous peroxide, on the other hand, may increase the glucose value by oxidizing the chromogen.

Commercial kits based upon this method (e.g. Sigma-Aldrich Co. Ltd, product number 510) consist of 5 U of glucose oxidase and 1 U of peroxidase per milliliter of enzyme solution and *o*-dianisidine as the chromogen. (**Caution:** *o*-dianisidine is a possible carcinogen.) The limit of detection by this method is reported to be 25 mg dL^{-1}. Correlation between this method and the *o*-toluidine method described above has been reported. The correlation coefficient was 0.9857 (data adapted from Sigma Technical Bulletin, Procedure No. 510).

To perform the above assays, conventional instrumentation is required. Any photoelectric colorimeter that transmits light in the UV to visible range can be used. For measurements involving the detection of reduced nicotinamide coenzyme, hexokinase method (UV measurement), UV transparent quartz cuvets should be used.

An interesting development with colorimetric methods of glucose determination has been the development of glucose test strips. In their simplest forms, the sample is placed on the test strip (which contains the necessary freeze-dried enzymes and buffer salts for the test) and a color develops. After wiping, the amount of color is checked against a reference chart and the concentration of glucose deduced. Alternatively, the amount of color formed can be measured using a hand-held spectrophotometer. This idea is used in the One Touch® glucose meter developed by Lifescan Inc. California, USA. In this device, once a drop of blood is applied to the target area of the test strip, a blue color is developed which is proportional to the concentration of glucose in the blood sample. After 45 s, the meter gives an accurate reading of the blood glucose levels. No wiping or timing is required thereby making the whole monitoring procedure easy to carry out. Calibration and quality control routines are supplied by the manufacturers thereby ensuring correct operation of the meter.

4 ELECTROCHEMICAL DETECTION OF GLUCOSE

4.1 Pulsed Amperometric Detection of Glucose

The electrochemical detection of organic molecules using a fixed voltage is most successful when the product of the electron-transfer reaction at the interface is stabilized by delocalization through a conjugated π system. Inspection of the glucose molecule reveals that such stabilization is not possible. This means that any free radicals formed by oxidation or reduction are high-energy species, that is they posses a high activation energy. Consequently, large overvoltages are required for the electrochemical conversion, which is a disadvantage in electroanalysis since it introduces serious interference problems.

One solution to this problem is to carry out the oxidation at a catalytic surface such as the surface of a platinum or other noble electrode. This ensures that the oxidation takes place at a moderate potential through a mechanism that involves adsorption of the glucose to a clean platinum or gold electrode. Unfortunately, the products of the catalytic oxidation can remain adsorbed to the electrode thus blocking the catalytic sites and preventing further oxidation (poisoning of the surface). Consequently, the response of such a system is characterized by a time-dependent diminution of the response. The deleterious effects of product adsorption can be reversed and the catalytic activity of the electrode surface restored by a two-step cleaning process. The triple-pulse waveform incorporates the amperometric measurement with a potentiostatic cleaning and reactivation of the surface within a single waveform (see Figure 2). The first pulse is at a potential where the electrocatalytic reaction takes place. Since this step passivates the electrode, the next pulse is at a more positive voltage. This results in the oxidative removal of passivating species. Concomitant with this is the formation of a surface oxide layer. The electrode is reactivated by removal of the oxide layer using a negative potential. The electrode is now ready for the next detection step. Because the mechanism of detection involves prior adsorption, the shape of the overall calibration plot reflects in some way the corresponding adsorption isotherm. To examine a general example of analysis by this method consider the steps involved in

Figure 2 Triple-pulse amperometric waveform for PAD of carbohydrates.

the oxidation of glucose in 0.1 M NaOH at a gold electrode. As the voltage is swept positive (oxidizing) glucose is oxidized at the surface of the electrode. At the same time, the electrode surface is oxidized to gold oxide which inhibits any further oxidation of glucose. On the reverse scan, the gold oxide is reduced and a fresh gold surface is formed. Concomitantly, any adsorbed by-products from the oxidation process are removed from the electrode and the sequential oxidation of glucose can recommence.

The integration of triple-pulse amperometry with ion chromatography systems has resulted in a very powerful set of analytical tools especially when CHOH-bearing compounds are measured. Indeed, PAD at gold electrodes is a reproducible and sensitive method for the detection of almost all carbohydrates of molecular weight up to 10 000. Carbohydrates can only be detected by PAD however in solution of high pH (>11). This concept of detection has been successfully commercialized by the Dionex Corporation. The effectiveness of this technique is best illustrated in Figure 3 which compares the reproducibility of chromatograms obtained using PAD (trace a) and a conventional fixed voltage detection methodology (trace b).

Alternatively, catalytic oxidation of glucose has also been reported using electrodes modified with cupric salts or fabricated from the metal itself. It has been proposed that these electrodes function via a mechanism involving the copper(III) oxidation state.[15] One major advantage of using copper electrodes is that the products of the oxidation do not adsorb to the surface. Therefore, no complicated cleaning regime is required, implying that these electrodes can be operated at a constant voltage. As with the noble electrodes, however, the oxidation process is only specific for the alcohol or aldehyde group. Therefore, there is no discrimination between glucose and other sugars or alcohol and chromatographic separation is required (see Figure 4).

Figure 3 Comparison of (a) PAD and (b) constant potential detection of a solution containing (l) lysine (30 ppm), (g) glucose (10 ppm) and (s) sucrose (40 ppm). *I* is the injection of sample.

4.2 Enzyme Electrodes

The enzyme electrode is a combination of any type of electrochemical probe with a thin layer (10–200 μm) of immobilized (insolubilized) enzyme. Typically, the progress of the enzymatic reaction (which is related to the concentration of analyte) is measured by monitoring the rate of formation of a product or the disappearance of a reactant. If either the product or reactant is electroactive, the reaction may be monitored directly using amperometry.

Because enzyme electrodes generally have the enzyme immobilized in a thin layer of some finite thickness on the surface of the probe, any modeling of the system response must consider the diffusional and partitioning effects of the enzyme layer. It is interesting to note that unlike solution reactions, where the rate is dependent upon a steady-state population of encounter complexes, with immobilized enzymes diffusion of the substrate to the enzyme is often, but not necessarily, the rate-determining step. Mass transfer by diffusion is a first-order reaction with respect to substrate concentration. Imposing a diffusional barrier thus has the effect of extending the linear range of initial reaction velocity beyond the K_M value of the soluble enzyme (cf. Figure 1). Because of this linear relationship, however, the observed rate of

reaction, and therefore analytical signal, is lower than would have been in a kinetically controlled enzyme reaction conforming to the rectangular hyperbola of Michaelis–Menten kinetics.

The proper functioning of an enzyme-based sensor is, therefore, heavily dependent on both the chemical and physical properties of the immobilized enzyme layer. To this end, there are many possible methods for immobilizing an enzyme at the surface of an electrode. For convenience, these can be divided into physical methods and chemical methods. An important consideration when developing an immobilization procedure is that the process should be applicable to a range of surfaces. This allows the choice of support to be as wide as possible and ensures that no refabrication of the support is required. Other advantages sought in the immobilization method include: (1) an ability of the biological component to operate at a wider pH range than in solution; (2) attainment of greater stability resulting from the immobilization and (3) the generation of a defined diffusion region on the surface of the electrode.

The enzyme most widely used for glucose detection in this context is the flavoprotein glucose oxidase. At the active site of this enzyme is a flavin moiety (flavin adenine dinucleotide) which exists either in the oxidized form FAD or in the reduced form flavin adenine dinucleotide (reduced form) ($FADH_2$). FAD oxidizes glucose to gluconic acid and the $FADH_2$ formed in the process is reoxidized by molecular oxygen (or an artificial electron acceptor) yielding hydrogen peroxide or the reduced form of the artificial electron acceptor.

In order to be used as a glucose sensor, glucose oxidase activity must be converted into an electrical signal. The earliest electrochemical glucose sensors were based upon the electrochemical monitoring of the decrease in oxygen tension (disappearance of one of the reactants) or the appearance of hydrogen peroxide (product formation). The accuracy of the first method is limited by the natural fluctuations in oxygen tension that result from changes in pH, temperature, ionic strength or partial pressure which means that the preferred method of choice is based upon peroxide determination.

The electrochemical detection of hydrogen peroxide is normally achieved by its oxidation at a platinum anode polarized at a potential of 0.5–0.6 V vs the silver/silver chloride reference electrode. The requirements for such a high operating voltage mean that the measurement at a naked platinum electrode is subject to interference by naturally occurring opportunistic species such as ascorbic acid, uric acid, glutathione, cysteine and paracetamol. Use of suitable membrane technology (cf. the Yellow Springs Instrument Glucose Analyser) means, however, that this approach has been successful for the detection of glucose.

4.2.1 Glucose Oxidase Method (Electrochemical Measurement)

4.2.1.1 Measurements using the Oxygen Electrode An oxygen electrode basically consists of a platinum cathode separated from the sample solution by a membrane which is selectively permeable to oxygen, e.g. Teflon™ or polyethylene. A second, pseudo-electrode consisting of silver/silver chloride in saturated potassium chloride is used to complete the electrochemical cell. When a voltage of −0.6 V vs the Ag/AgCl reference electrode is applied the amount of current that flows in the external circuit is related to the partial pressure of oxygen in the sample via the relationship, Equation (14)

$$i = nF\alpha_m pP_s \left(\frac{D_m}{b} \right. \tag{14}$$

where n, the number of electrons involved in the reduction step = 4, F is the Faraday constant, α_m is the solubility of oxygen in the membrane phase, pP_s is the partial pressure of oxygen in the sample, D_m is the diffusion coefficient of oxygen in the membrane phase and b is the membrane thickness. Since diffusion through the membrane is likely to be the slowest contribution to the overall process, the response time, t_r, of an oxygen electrode can be approximated to (Equation 15)

$$t_r \approx \left(\frac{b^2}{D_m} \right. \tag{15}$$

The instrumentation required for this assay method is a commercially available oxygen electrode (Rank Brothers, Cambridge, UK).

4.2.1.2 Measurements based on Hydrogen Peroxide Detection An alternative approach to monitoring the glucose oxidase reaction electrochemically is to measure the production of hydrogen peroxide. Hydrogen peroxide is electroactive and can be conveniently measured by oxidation at a platinum anode according to Equation (16).

$$H_2O_2 \longrightarrow 2H^+ + O_2 + 2e^- \tag{16}$$

This approach forms the basis of instruments often referred to as glucose analyzers. Several are commercially available, e.g. the Yellow Springs Instrument Company Sensor,[16] and although the design varies from one manufacturer to another, a common feature is that the glucose oxidase is immobilized either as a membrane or in a packed bed thus allowing multiple measurements. In order to prevent interference from the oxidation of extraneous substances present in the sample, e.g. ascorbate, urease, tyrosine, paracetamol, glutathione and so on the anode is usually covered by a thin Nucleopore™ polycarbonate/cellulose acetate combination membrane. In

this configuration, the porous polycarbonate membrane limits the diffusion of glucose into the enzyme layer thus preventing the reaction from becoming enzyme-limited. Cellulose acetate permits only small molecules such as hydrogen peroxide to reach the electrode thereby eliminating many electrochemically active compounds that would interfere with the measurement. Alternatively, the response can be compensated by a nonenzymatic detector and the difference current used to calculate the true concentration of glucose. A summary of some of the commercially available glucose analyzers is given in Table 3.

Unlike peroxide measurement which starts from a very low basal level (no peroxide present) and permits a sensitive detector (detection limit ca. 1 μM), in the case of oxygen reduction a decrease in signal is monitored in response to glucose. Consequently, the sensitivity to glucose by this method is lower by two or three orders of magnitude.

4.2.1.3 Mediated Electrodes An alternative approach is to use oxidants other than molecular oxygen to regenerate the catalytically active flavin coenzyme. The ideal method would be direct electron exchange from the active site of glucose oxidase to the electrode surface but this is not possible since the active site is embedded in the protein and the distances involved are hence too great. Thus, electron transfer must be achieved through the use of mediators. Because of many desirable chemical and electrochemical properties, ferrocenes have been the most successful class of mediators to date. The simulated cyclic voltammograms of a glucose sensor based upon the combination of glucose oxidase with ferrocene is shown in Figure 5. In the absence of glucose (a), the reversible cyclic voltammogram of ferrocene is observed. When glucose is present (b), the response changes. The voltammogram displays an increase in oxidation current and the disappearance of the reduction wave, which is characteristic of catalytic reduction of ferrocenium by glucose oxidase.

This approach has been commercialized to make disposable glucose sensors for self-monitoring for diabetic patients. The Exac-Tech pocket-sized meter (MediSense, Abingdon, UK, and Bedford, MA, USA) is designed for mediated amperometric determination of glucose in capillary whole blood. It consists of a pen-shaped barrel, housing a custom-built single chip microprocessor, sealed power source liquid crystal display and operating button. The sensors are ferrocene-mediated glucose oxidase electrodes screen printed onto a plastic substrate. Several print runs are involved laying down silver impregnated carbon ink for electrical connection, and using a silver/silver chloride reference electrode, a carbon working electrode containing glucose oxidase and a ferrocene derivative. The construction is completed by a coarse gauze spreading layer covering the two electrodes. The enzyme electrodes respond to capillary blood glucose concentrations in the range 2.2–25 mM.

Because the spreading layer does not act as an anti-interference layer, the electrodes are prone to interference. A urate concentration of 700 μM, for example, causes an increase in the apparent glucose reading of 3 mM which could be clinically misleading to a diabetic. Capillary blood samples containing 700 μM urate are, however, rare. Paracetamol also interferes with the measurement but only at levels associated with overdose. Salicylate, acetone and acetoacetate also interfere but the effects are not clinically significant.[17] Typical responses to glucose utilizing these electrodes in this laboratory are shown in Figure 6. A more recent design of the mediated-glucose sensor is Medisense Card Sensor which has the approximate dimensions of a credit card. The operation

of this device is similar to the Exac-Tech Pen described above with the exception that once the drop of blood is applied to the target area of the glucose electrode, the blood glucose test starts automatically.

Figure 6 Transient responses to increasing concentrations of glucose obtained using commercially available glucose/ferrocene strip electrodes. The inset shows the calibration graph. Current values represent the response of the sensor after 30 s. The correlation coefficient using these electrodes was 0.999. (Data courtesy of Mr Kenneth McKeegan, Ph.D student, University of Paisley.)

Another successful approach involving mediators has been the ''wired'' enzyme electrode. Here, the mediators tend to be osmium bipyridine complexes which are cationic in nature and hence bind electrostatically to the anionic glucose oxidase molecule. This allows efficient exchange of electrons between the osmium centers of the complex and the active site of the enzyme via the mechanism of electron hopping. If one of the coordination sites of the osmium complex is occupied by the N-atom of an imidazole or pyridine moiety of a polyvinylimidazole or polyvinylpyridine polymer, then the mediator can be retained at an electrode surface in a three-dimensional polymer network. If the glucose oxidase is also entrapped within this network, electron hopping still occurs and the catalytic activity can be measured electrochemically. The advantage of this approach over the ferrocene-mediated case described above, is that the sensor is more stable because the mediator is physically retained at the electrode surface.

As mentioned above, one method of detecting glucose using the enzyme glucose oxidase is to measure the hydrogen peroxide produced at a platinum electrode. An alternative approach to peroxide detection is to use an enzyme electrode based on ''wired'' horseradish peroxidase. Here, coordinated osmium complexes are again used as the mediator. The wired peroxidase electrode can be used for the detection of glucose following separation by LC. As an illustration, its performance is compared with a traditional platinum electrode in Figure 7. In a typical experimental set-up, the sample containing glucose, ascorbic

Figure 8 Components for the chromatographic separation and detection of glucose using either a platinum anode or a ''wired'' peroxidase enzyme electrode detector.

acid and uric acid is first passed through a reversed-phase chromatographic column. The eluant is then passed through a reactor column containing immobilized glucose oxidase which oxidizes the glucose and produces hydrogen peroxide. The peroxide is detected downstream either at a wired peroxidase electrode or a conventional platinum anode. This arrangement is summarized in Figure 8. Points to note with the wired electrode are (1) the sensitivity and detection limits for glucose are better than with the naked platinum detector, (2) the electrode is more stable than the platinum anode, (3) because of the lower operating voltage, the wired enzyme detector is less prone to interference and (4) the equilibration time for the peroxidase electrode is reportedly shorter than that required for the platinum electrode.[18] Instrumentation as well as the wired peroxidase enzyme and the packed glucose oxidase reactor column are available from Bioanalytical Systems Inc., West Lafayette, USA.

5 CONCLUSIONS

This article has discussed various analytical methodologies for the quantification of glucose. For convenience, these have been classified as traditional colorimetric methods involving the use of spectrophotometers or electrochemical approaches. I have, however, limited myself to only those methods which are commercially available. Where possible, reference has been made to technical information supplied by the manufacturer of the analytical procedure.

Immunochemistry is a generic term to describe all analytical methods that employ the reaction between an antigen and its complementary antibody for the recognition and/or quantitation of an analyte. The analyte may be the antigen or antibody and in each case the complementary species (antibody or antigen, respectively) will be the primary reagent in the analytical system. The analyte may be present in free solution (e.g. in blood, urine, fermentation broth, effluent, etc.) or may be structurally incorporated in a cell (e.g. red cell, bacterium, virus particle) or solid tissue. Our knowledge of the chemical structure and reactivity of the combining sites of antigens and antibodies (epitopes and paratopes, respectively) has meant that antigen- and antibody-like species can now be synthesized. In the former case this may be undertaken to provide an appropriate immunogen or calibration material whilst several antibody mimics have been demonstrated.

The immunoassay format will depend on the purpose for which the assay is to be used. In that the antigen–antibody reaction is unique to two complementary partners, in terms of cells and tissues, there is no other technique that will provide the same specificity – with the exception of DNA. Quantitative assays are usually required for the analysis of molecules in complex fluids. In the research phase, chromatographic techniques, e.g. high-performance liquid chromatography (HPLC), gas chromatography (GC), or capillary zone electrophoresis (CZE) can provide the characterization and quantitation required; however, these techniques are not always applicable when the need for the assay is established and a large workload is envisaged. An immunoassay then provides the necessary specificity and workload capability. In addition, when assays are used outside the laboratory, e.g. at the bedside, then only immunoassays are applicable because they can be encapsulated in microfabricated devices.

This article describes the underlying principles of immunoassay, the design of reagents and assay formats, and illustrates their application to a wide range of analytes.

1 INTRODUCTION

Immunochemistry is a term that embraces all aspects of the reaction between an antibody and its complementary antigen. The production of an antibody is a biological phenomenon and represents the product of a response of a higher vertebrate (the immune response) to the

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

presence of a foreign species (the immunogen or antigen). The antibody that is produced binds tightly to the foreign species, thereby hastening its removal from the circulation. The tightness of this binding is a result of the complementarity between the antigen and the antibody molecules – in terms of chemistry (i.e. thermodynamics) and spatial orientation (i.e. topography of molecular surfaces).

Immunoanalysis describes any technique that utilizes an antibody or antigen in order to recognize (and quantitate) its complementary partner (namely the antigen or antibody, respectively). Whether the purpose is characterization or quantitation of a species (the analyte of interest), the quality of assay performance is primarily dependent on the nature of the antibody or antigen employed as the primary capture or recognition reagent.

The reaction between antigen and antibody is the result of an array of chemical interactions which are easily modified by the nature of the reaction milieu, and consequently reagent design and optimization are a vital feature in ensuring good analytical performance.

The following discussion will focus on a description of current knowledge of the antigen–antibody reaction, on the production of an antibody preparation, and on the design and optimization of immunoanalytical systems. Finally, examples will be given to illustrate the range and quality of assay performance that can be expected.

2 THE ANTIGEN–ANTIBODY REACTION

The product of the immune response in higher vertebrates is a family of antibodies that bind to varying degrees (in terms of both avidity and site on the surface of the molecule) to the antigen. Antibodies comprise a family of proteins known as immunoglobulins; the immunoglobulins are heterodimers of a similar architecture. The basic unit comprises two heavy chains of about 450–600 amino acid residues and two light chains of about 220 residues; the chains are linked by disulfide bridges (Figure 1). In mammals there are five immunoglobulin classes, IgG, IgA, IgM, IgD, and IgE; they differ in the amino acid sequence and carbohydrate content of the heavy chains. There are a total of nine heavy-chain isotypes; however, there are only two types of light chain, kappa and lambda. In the case of IgA and IgM the molecules are dimeric and pentameric versions of the basic immunoglobulin molecule with extra of additional residues, secretory component with J chain and J chain, respectively. IgA generally exists in monomeric form in the circulation.

Figure 1 Representation of the immunoglobulin G molecule indicating heavy and light chains, variable and constant domains (V and C), and hypervariable regions (▩). Solid lines denote disulfide bridges.

The antigen-binding region of the immunoglobulin, known as the paratope region, is located in the amino-terminal domain of the heavy and light chains. In these regions there are so-called variable regions, and within each of these variable regions there are three regions of hypervariability which constitute the complementarity-determining regions (CDRs) of the immunoglobulin.[1] It is the variability of amino acid residues in the CDRs that imbue the antibody with unique specificity for an antigen or antigenic region of a molecule.

2.1 Molecular Chemistry

The basic structure of the immunoglobulin molecule is in the form of two β-pleated sheets of strands in antiparallel directions linked by a disulfide bridge. In the paratope region of the immunoglobulin the variable element of the heavy and light chains associate noncovalently to form a β-barrel structure that brings the six CDR close together; it is this colocation that creates the antigen-binding pocket or paratope region. Both the length of the CDRs and the amino acid sequences are variable.

Detailed analysis of the chemistry and structure of immunoglobulins and analysis of antigen–antibody interactions using techniques such as X-ray diffraction suggest that the region of the antigen (the epitope) that is in contact with the immunoglobulin is about 700–900 Å in area made up of 15–22 amino acid residues within the immunoglobulin. The paratope comprises a limited number of residues originating from most or all of the CDRs; about half of the CDR residues are aromatic.[2] It is suggested about one third of the CDR residues may contribute to a unique paratope and it has been shown that more than one unique paratope may exist within one antigen-binding pocket; more commonly, epitope sites may overlap, although concurrent binding of respective paratopes (i.e. antibodies) will not happen in practice owing to steric hindrance.

The region of the antigen that binds with the antibody is known as the antigenic-determining region or epitope. In the case of a macromolecule such as a protein, it will constitute an area and number of residues similar to that of the paratope. The epitope may comprise a series of either continuous or discontinuous residues, more commonly the latter. Thus the reaction between antigen and antibody will depend not solely on the chemical structure of the residues but also on the spatial configuration.[3,4] This is an important observation because purification of a macromolecule in order to use it as an immunogen may destroy the unique epitope and result in no functional antibody being produced; it is also an important consideration in the use of a synthetic peptide as an immunogen. It has been suggested that in a macromolecule the epitope involves only a few residues and equates to a hapten size of the order of 400–500 Da; these data are supported by studies of affinity constants for haptens of different sizes in which little increase is seen for haptens of about 500 Da.[5]

2.2 Thermodynamics

In aqueous solutions molecules exist as discrete entities by virtue of a surrounding hydration shell of water molecules; thus in the case of proteins the loss of the influence of the hydration shell leads to aggregation and precipitation of the protein molecules. The repulsion between protein molecules in order to keep them apart (i.e. in solution) operates over a distance of 20–30 Å and the primary forces of attraction between the epitopic region of an antigen and the complementary paratope region of the antibody must overcome this barrier. Thus the energy of attraction at a distance of 30 Å must be sufficient to overcome the hydrophilic forces of repulsion.[6]

There are four types of attractive forces involved in the antigen–antibody reaction. The major forces in the initial or primary reaction are due to hydrophobic and electrostatic interactions. The hydrophobic force is the result of the tendency of nonpolar residues to aggregate when immersed in water. The strong hydrophobic forces of the CDRs are therefore complementary to the predominantly hydrophilic pattern of residues within the epitope region. The electrostatic interactions result from the ionized species of the epitope and the oppositely charged species of the paratope. The force of the interaction is inversely proportional to the distance between the charged groups and also depends on the ionic strength of the surrounding milieu. Thus in more dilute salt solutions electrostatic forces operate over greater distances than in a solution of high ionic strength.[7]

The hydrophobic and electrostatic forces of the primary reaction will draw the antigen and antibody surfaces together and then the secondary van der Waals interactions and hydrogen bonding come into play. Thus whilst the primary forces can influence over distances of 30–100 Å, the secondary attractive forces are only effective over distances of 2–10 Å, with hydrogen bonding being over the shorter distances. Hydrophobic interactions are also important in the secondary phase of the antigen–antibody reaction involving the ''squeezing out'' of water molecules that surround the surface of both epitope and paratope regions.[8,9]

In the latter stages of the reaction and, in part, depending on the size of the antigen there may be further interactions involving part of the molecules outside of the complementary epitope : paratope regions. This can result in aggregation of the molecules, attested to by the fact that it can become increasingly difficult to dissociate the complexes.

2.3 Kinetics

Whilst the reaction between antigen and antibody may be complex, the complexity is dependent, in part, on the size of the antigen molecule. It can be described in a simple equation derived from the law of mass action. Thus the reaction can be described as Equation (1):

$$\mathrm{Ag} + \mathrm{Ab} \underset{k_d}{\overset{k_a}{\rightleftharpoons}} \mathrm{Ag:Ab\ complex} \tag{1}$$

where k_a and k_d are the association and dissociation constants, respectively. The association (K_a) and dissociation (K_d) constants at equilibrium are then described by Equations (2) and (3):

$$K_a = \frac{k_a}{k_d} = \frac{(\mathrm{Ag:Ab})}{[\mathrm{Ag}][\mathrm{Ab}]}\,\mathrm{L\,mol^{-1}} \tag{2}$$

$$K_d = \frac{k_d}{k_a} = \frac{[\mathrm{Ag}][\mathrm{Ab}]}{(\mathrm{Ag:Ab})}\,\mathrm{mol\,L^{-1}} \tag{3}$$

This is a simplified view because, whilst it is important to recognize that the antigen–antibody interactions are reversible, the energy of the dissociation step is usually higher than the energy of association, particularly when the secondary bonding formation has occurred. This observation is known as hysteresis[6] and is more applicable to complex antigens reacting with their complementary antibody molecules, i.e. more applicable to proteins than haptens.

The association and dissociation constants of the reaction give a measure of the affinity constant, equivalent to the equilibrium constant, and will have an important influence on the design of an immunoassay. Strictly the affinity constant of an antibody should be equated to the association constant of the primary reaction, but in practice the contribution of the secondary association reaction and the influence of dissociation will contribute to the observed value. In the case of a polyclonal

antiserum the situation is further complicated because the observed affinity constant will be a composite measure of the primary association and dissociation constants of the range of individual antibodies. Thus in a heterogeneous immunoassay, using a polyclonal antiserum, the presence of antibodies with a low association constant and/or high dissociation constant will have little impact on the observed reaction. Antibodies with a high dissociation constant will be of little value in a heterogeneous immunoassay because the antigen–antibody complex will dissociate during the washing step.[10] When considering the design of an immunoassay, antibody affinities up to 10^{12} L mol^{-1} are achievable, although in practice the majority of antibodies that are employed possess affinities within the range of 10^7–10^9 L mol^{-1}.

A range of techniques have been employed to study antigen–antibody interactions; they all depend on a characteristic of the reactants or products of the reaction and include spectroscopic, chromatographic, sedimentation, and calorimetric methods. The most commonly used methods are enzyme-linked immunosorbent assay (ELISA), calorimetry, and optical biosensing.

In the case of ELISA, antibody at a fixed concentration is incubated with various concentrations of antigen; at equilibrium the mixture is then transferred to another tube coated with antigen. The free antibody binds to solid-phase antigen and after washing is determined with the aid of a labeled second antibody. In this method labeling of the primary reactants is avoided.[11] This technique cannot be used for kinetic analysis.

The heat of reaction is used to measure the amount of complex in calorimetry, with titration by antigen at a fixed antibody concentration or vice versa. The method is not sensitive enough for affinities higher than 10^8 L mol^{-1} and cannot be employed for kinetic analysis.[12]

The major development in this field is the introduction of surface plasmon resonance techniques.[13] The technique permits real-time monitoring of binding, facilitating the assessment of both kinetics and concentration of analyte. The method depends on the change in refractive index at the optical surface, and so is more suited to binding of antibody or high-molecular-weight antigen. However, the binding of a hapten from solution can be assessed by using a high-molecular-weight label, e.g. a latex particle.[14] There are important issues to consider in this approach to kinetic analysis, including (1) the effect of coupling one of the species (antigen or antibody) to the optical surface on the conformation of the bound species, (2) the influence of the proximity of the surface on binding, (3) the effects of mass transfer, namely the diffusion effects, and (4) the influence of sample depletion immediately surrounding the immobilized reactants.[15] These factors can be taken into account and there is no doubt that this type of real-time reaction monitoring has contributed a great deal to our knowledge of antigen–antibody interactions.[16]

2.4 Factors that Influence the Antigen–Antibody Reaction

The rate and strength of the reaction between antigen and antibody are determined by the complementarity of the epitope and paratope regions, respectively, being modified to various degrees by other constituents of the reaction milieu. Bearing in mind the earlier discussion on molecular chemistry, the reaction characteristics are determined by the sequence of chemical substituents, the nature of the intermolecular forces of attraction and repulsion, and the spatial disposition of the reactive substituents. The basic reaction takes place in two phases; the first is rapid, specific and reversible and involves overcoming the repulsive forces between antigen and antibody. The reactions involve hydrophobic and electrostatic interactions; as an example, the reaction can be inhibited by increasing the pH beyond 10 in most instances. The secondary reaction involves hydrophobic interactions again, in addition to van der Waals force and hydrogen bonding. Thus, conditions that remove the water shield around molecules will enhance the rate of reaction. However, in considering all of the forces of interaction there may be little apparent difference between the specific antigen–antibody reaction and the nonspecific interaction between molecules; thus in many cases reaction conditions that promote the rate of reaction between protein and antibody will also tend to promote nonspecific protein precipitation, e.g. the use of ammonium sulfate and poly(ethylene glycol).

The charge on the surface of paratope and epitope regions clearly plays an important role in the initial primary binding reaction and thus the pH of the reaction environment, the nature of the ionic species, and the ionic strength are all important. It should also be recognized that these characteristics will also have an effect on the conformation and stability of the proteins present. In addition, the concentration of the constituent antigen and antibody species will also have an important influence on the speed of the reaction and on the colloidal stability of the complex formed. Hence most immunoassay reactions are performed around pH 7; at lower pHs there is a tendency for nonspecific association between protein molecules to occur with little specific binding. At higher pHs the nonspecific effects are less evident although the specific effects are also less than at pH 7.[17]

The nature of the ionic species plays an important role in both specific and nonspecific reactions and whilst considerable variation is seen there are general observations that can be made. There is a chaotropic series of anions (the Hofmeister series) in which phosphate is

known to be antichaotropic and thus promote association whilst certain amino acids and amino alcohols, borate, and thiocyanate are chaotropic.[18] Phosphate buffers can therefore be used successfully whereas buffers containing glycine or borate, whilst good for storing reagents, yield poor reaction characteristics. These observations are particularly true for immunoagglutination reactions where the concentration of constituents is often higher than in labeled heterogeneous assays. Polymers such as the poly(ethylene glycol)s can increase the rate of reaction in many systems, again particularly in the case of the agglutination reactions. It is thought that they act by removing water molecules from the immediate environment surrounding the epitope and paratope regions, promoting binding.[19]

Finally, although often not considered to be important (say compared with the effect on enzyme activity), temperature can have a major influence on the rate of the antigen–antibody reaction. The major effect will be on the rate of diffusion, and thence collision, of reactants.

3 PREPARATION OF ANTIBODY REAGENTS

Immunochemistry is founded on a natural biological phenomenon and the early developments were all based on the use of polyclonal antisera: such preparations containing a population of antibodies varying in their affinity and thence specificity for the antigenic partner. The development of monoclonal antibodies by Kohler and Milstein in 1975[20] revolutionized the whole field of immunoreagents, and the advent of antibody engineering has taken this process of refinement a stage further. It should be evident from the earlier discussion that considerable research has been devoted to the molecular chemistry of the antigen–antibody reaction and it is therefore not surprising that synthetic chemists have developed a range of options for producing antibody mimics. However, today the majority of reagents are still based on polyclonal or monoclonal antibody preparations.

3.1 Immunogen

Generally a molecule needs to be greater than 3000 Da in size to produce an antibody response, and in order to produce a polyclonal antiserum a purified preparation of antigen is required. In the case of low-molecular-weight antigens a carrier molecule is required in order to achieve a response; typical carriers include bovine serum albumin, keyhole limpet hemocyanin and thyroglobulin.[21] In the case of large macromolecules, where a unique specificity is required, synthetic peptides have been employed to achieve the desired complementarity. When producing a monoclonal antibody the purity of the immunogen is less important theoretically, because the specificity can be selected at the time of subcloning.

3.2 Polyclonal Antisera

It is worth considering the immune response for a moment when a ''foreign antigen'' enters the bloodstream of a higher mammal. The initial response is the expansion of antigen-specific T and B lymphocytes with the production of a small amount of immunoglobulin M followed by the production of immunoglobulin G (the primary response). The introduction of a second bolus of immunogen leads to a secondary response with the differentiation of the B cells into plasma cells and the production of larger amounts of immunoglobulin G. The result will be a mixed population of antibodies reflecting specificity for different parts of the antigen molecule.

A range of mammals have been used for the production of antisera including mice, rabbits, goats, and sheep. A wide range of immunization protocols have been described based on the injection of a preparation of antigen dissolved in an adjuvant (e.g. complete Freund's adjuvant). A second injection may be given after several days (e.g. 14) and a third after a similar period. The animal may be bled after 21 days (e.g. in the case of a mouse) to determine the presence and titer of antibody response with blood collection for antisera after about 5 weeks.[22]

The wide range of protocols encompass a host of conditions that research workers have found optimal for their applications, including the exact nature of the immunogen, the type of adjuvant, the type and strain of animal, the route of immunization, and the timing of injections. The choice of animal will often depend on the amount of antiserum required.

3.3 Monoclonal Antibodies

The core of the production of monoclonal antibodies is the fusion of the immune spleen cell with a myeloma cell.[20] In order to achieve this the spleen is removed from the immunized animal (typically a mouse and about 35 days after the initial immunization) and teased into a single-cell suspension. The spleen cells are gradually mixed with the myeloma cells in the presence of poly(ethylene glycol) to promote fusion. The suspension is then diluted in first a serum-free and then a serum-containing medium. The fused cells are then cultured in a large number of wells containing growth medium incorporating hypoxanthine, aminopterin, and thymidine (HAT), which induces apoptosis in the non-fused cells, which die. The fusion preparation is then fed every few days for about 3 weeks until confluent

growth is achieved.[23] The supernatant from the fused hybridoma preparation can then be used to screen for the presence of antibody. A range of techniques can be used for screening, depending on the antigen, including radioimmunoassay, ELISA, antibody capture, and Western blotting.

Once the antibody-producing cells have been identified, it will be necessary to employ subcloning, to ensure monoclonality, and cryopreservation. The subcloning also helps to stabilize cell growth and prevent the overgrowth of nonsecreting cells; it is most commonly achieved by limiting dilution. Large-scale production of antibody can then be undertaken either in vivo by growth in the peritoneal cavity of the animal (most usually when the mouse is employed for immunization) or in vitro using cell culture. Many techniques have been described for the production of large amounts of antibody by cell culture with downstream processing to achieve purified material.[24]

3.4 Antibody Engineering

As knowledge of the structure and genetics of the immunoglobulin molecule has increased and with the ability to manipulate DNA, it has become possible to engineer recombinant molecules. A number of genetic modifications of the immunoglobulin have been described, the best known being the humanizing of the molecule to facilitate therapies employing antibodies.

One of the techniques that has been described for the modification of antibody molecules used for diagnostic purposes employs the production of a single-chain antibody.[25] This is based on the isolation of the Fv fragment of the antibody which can then be cloned by standard recombinant techniques with expression of the genes coding for the V_H and V_L domains stabilized with a peptide bridge sequence. Modification of the nucleotide sequence by, for example, site-directed mutagenesis, can then be used to change the CDR, thereby altering the specificity of the recombinant antibody.[26]

Bivalent or bispecific antibodies have also been produced using genetic engineering, one option being the linkage of two single-chain antibodies. An antibody fragment can also be used to create a fusion protein with another protein or fragment; the fusion of antibody fragments with enzymes has been described by several research groups.[27]

An alternative approach to engineering of an antibody from an existing hybridoma is to obtain novel antibody specificities from a gene library using phage display technology. In addition to the opportunity to obtain novel specificities, this approach offers an alternative to polyclonal or hybridoma technology.[28]

3.5 Molecular Imprinting

Knowledge of the chemical substituents and reaction mechanisms harnessed in the complementary epitope and paratope regions has facilitated the creation of a paratope pocket in a polymeric matrix. Initially monomers are chosen that are capable of interacting with specific residues of the molecule of interest. A second cross-linking monomer is then added that fixes the ''recognition monomers'' that are bound to the imprint molecule of interest. If this imprint molecule is then removed (e.g. by use of a solvent), an imprint cavity is left which is then capable of participating in a competitive reaction similar to an antibody molecule.[29] A heterogeneous population of binding pockets is created in the polymeric structure and affinity constants of $10^9\,L\,mol^{-1}$ are achieved with a limit of detection of hapten of $6\,nmol\,L^{-1}$ being demonstrated. Assays have been described for a range of hapten molecules such as morphine and theophylline, giving comparable results with established methods.[30]

3.6 Aptamers

Aptamers are nucleic acid molecules that bind ligands and are derived from the selection of random sequence pools of oligonucleotides of DNA or RNA molecules.[31] Modifications to this approach, known as systematic evolution of ligands by exponential enrichment (SELEX), has further expanded the opportunities for exploitation; these have included the use of partial randomized pools as the starting point for defining functional sequences, the introduction of modified oligonucleotides to stabilize the aptamer molecule, and the ability to link them to signal molecules.[32] However, the major advantage is the ability to build combinatorial libraries of compounds that can then be evaluated for their binding properties, and then the preferred sequence enriched using the polymerase chain reaction. Examples include aptamers that inhibit enzymes such as human neutrophil elastase and human thrombin. Antiprotein kinase C aptamers have been demonstrated in the equivalent of a ligand binding assay,[33] whilst an aptamer that was bound to vascular endothelial growth factor was synthesized with a fluorescein molecule coupled to its 5′ end; the antigen was subsequently detected by use of antifluorescein antibody labeled with alkaline phosphatase.[34] Fluorescein-labeled aptamers directed against human neutrophil elastase have also been used in flow cytometry.[35]

Experience to date indicates that aptamers possess binding affinities similar to those of antibodies. They may therefore provide an alternative means of producing the paratope pocket which can be produced in bulk and is applicable to toxic molecules and molecules that are not strongly immunogenic.[36]

4 LABELS USED IN IMMUNOCHEMISTRY

Immunochemical reactions are employed for the recognition and (possibly) quantitation of the substance of interest. In both of these applications it is necessary to detect the binding of antibody to antigen; the majority of immunochemical techniques that have been developed have required the use of a label of either antigen or antibody to detect the presence and extent of the reaction.

4.1 Radioisotopes

The first label described for an immunoassay was iodine-131 in a radioimmunoassay for insulin. The most commonly used labels in quantitative immunoassays have been iodine (^{125}I), carbon (^{14}C), cobalt (^{57}Co), selenium (^{70}Se) and tritium (^{3}H). The carbon and tritium isotopes emit β charged particles (radioactivity); the charged particles arising from the radioactive disintegrations are absorbed by a phosphor and converted into light which is then detected by a photomultiplier tube. The phosphors are organic compounds with examples being anthracene and naphthalene; it is common for mixtures of phosphors to be used. As the amount of energy produced is low the isotope and phosphor need to be in close proximity and the sample is therefore dissolved in a solution containing the phosphor (liquid scintillation counting).[37]

The cobalt, iodine, and selenium isotopes emit λ charged particles and this radiation is detected using inorganic phosphors such as thallium-activated sodium iodide crystals which are optically coupled to a photomultiplier tube. A feature of the use of λ radiation has been the design of multihead γ counters which greatly speed up the process of counting batches of tubes; subsequently a few fully automated immunoassay analyzers incorporating isotope counting were developed.

The choice of label depends in part on the sensitivity required for the assay and the nature of the labeled species. Thus the larger iodine molecule can be used for labeling proteins with attachment well away from the epitope or paratope region whereas carbon or tritium labels are required for smaller hapten molecules in order to preserve the epitope region. The iodine label is used because it can be readily incorporated into many molecules through the use of the cationic iodine species produced by the oxidation of iodide; a typical oxidant used is chloramine T, lactoperoxidase, or iodogen. In the iodination of proteins it is usually effected through the tyrosine residues present. An alternative approach, if there are no tyrosine residues present, is to conjugate a molecule containing the radioiodine to the compound of interest – pure antigen in most instances. A typical conjugation molecule is that described by Bolton and Hunter, i.e. radioiodinated *N*-succinicimidyl-3-(4-hydroxyphenyl) propionate, which reacts with primary amine groups.[38] Tritium labeled compounds are produced either by direct chemical synthesis or isotope exchange reactions.

The production and use of radioisotopes are heavily regulated and it is for this reason that alternative labels have been sought.

4.2 Enzymes

The choice of an enzyme as a label is logical because of its role as a biological catalyst. However, an enzyme provides the additional flexibility because of the alternative substrates available that enable the use of different detector technologies.

4.2.1 Choice of Enzyme

The choice of enzyme is primarily determined by the availability of a purified preparation, the stability of the enzyme in both a purified and diluted form and also during the conjugation process and when conjugated, together with the type of substrates available and the ease of detection of product.[39] In the case of a homogeneous assay (discussed later), the enzyme of choice must not be present in the sample, in order to avoid interference from endogenous enzyme during measurement. A list of some of the enzymes employed in immunoassays is given in Table 1.

4.2.2 Conjugation of Enzymes

A range of protein conjugation techniques have been described for coupling the enzyme to the antigen or antibody molecule; the final choice is based on what is shown to work but preservation of the enzyme activity and protection of the epitope and paratope

Table 1 A few examples of the enzymes commonly employed in immunoassays

Enzyme	Product	Detection
Alkaline phosphatase	Nitrophenol	Absorbance
	Methylumbelliferone	Fluorescence
	Dioxetane derivative	Luminescence
	Aminophenol	Electrochemical
β-Galactosidase	Nitrophenol	Absorbance
	Methylumbelliferone	Fluorescence
	Dioxetane derivative	Luminescence
Glucose oxidase	Oxidized dye	Absorbance
Glucose-6-phosphate dehydrogenase	NADH	Absorbance
	NADH	Fluorescence
	NADH	Luminescence
Peroxidase	Oxidized dye	Absorbance
	Oxidized luminol	Luminescence

NADH, reduced nicotinamide adenine dinucleotide.

regions are obviously critical. The most commonly used methods employ either glutaraldehyde or a range of heterobifunctional compounds. In the former the five-carbon dialdehyde homofunctional molecule links protein molecules through lysine ε-amino and N-terminal groups. The obvious disadvantage of this approach is the opportunity for cross-linking between enzyme molecules, thereby reducing the yield of conjugate.

The heterobifunctional linker molecules offer a wider range of residues for coupling but also the choice of two reaction conditions such that only one group is activated at a time, reducing the potential for cross-linking of enzyme molecules. Compounds that have been described for enzyme protein conjugation include *N*-(4-aminobenzoyl)-*N*′-(pyridyldithiopropionyl)hydrazine (ABDP), *N*-[β-(4-diazophenyl)ethyl]maleimide (DPEM), *N*-hydroxysuccinimidyl 4-azidobenzoate (HSAB), and *m*-maleimidobenzoyl *N*-hydroxysuccinimide (MBS); a larger list is given by Gosling.[40]

In the case of hapten molecules, conjugation has also been employed through phenolic, imidazole, and carboxyl groups. In addition, a spacer molecule may be incorporated to reduce the shielding of the epitope site; however, the length of this spacer can be critical. The most commonly used conjugation schemes employ carbodiimide, which is used to form an active *N*-succinicimidyl ester from the carboxyl-containing hapten and *N*-succinimide.

4.2.3 Recombinant Molecules

The fusion of enzymes with antibody or other acceptor molecules has been described, although not for many immunoassays.[41]

4.2.4 Signal Technologies

Many of the enzymes described earlier can be measured using a range of substrates, the choice being determined by the environment in which the assay might be used, the type of assay, the concentration range of detection required, and the nature of the sample, together with the practical issues of reagent costs, reagent stability, and instrumentation available.

Thus if the detection takes place in or on the surface of a solid matrix (e.g. gel, biopsy section) then it is important to choose a substrate that will permit the generation of a high color yield and insoluble product that remains associated with the matrix after formation.[42] Colorimetric detection will depend to some extent on the instrumentation involved but the molar absorptivity of the product and the absorbing wavelength will be the major guiding criteria. The most commonly used substrates have been nitrophenol derivatives with an absorbance maximum of the product at 405 nm or redox dyes with absorbance maxima in the 500–600 nm region. The latter is more applicable for visual detection by the naked eye.

Fluorescent and luminescent products are also popular, albeit requiring more specialist equipment for detection. Methylumbelliferyl derivatives have often been employed with alkaline phosphatase and β-galactosidase labels.[43] Luminescent detection systems have been described for alkaline phosphatase, β-galactosidase and horseradish peroxidase, in the former case with the synthesis of a wide range of compounds based on adamantyl derivatives.[44] Enhanced luminescence has been very effective in improving the light yield, particularly in the case of the luminol peroxide reaction, with molecules such as *p*-indophenol and *p*-phenylphenol increasing the light yield (by over 1000-fold) in addition to prolonging the period of light emission.[45] The luminescent detection systems have proved to be extremely valuable in immunocharacterization techniques (immunoblotting) with the position of the label being detected using X-ray film.

In the situation where a relatively opaque reaction medium is encountered, e.g. when using a whole blood sample, it may be appropriate to use a substrate capable of generating an electrochemically active product. These products include phenol, *p*-aminophenol, and NADH.[46]

4.2.5 Enzyme Amplification

Whilst it is possible to obtain improved sensitivity of detection by the choice of substrate and detector technology, this can also be achieved by the use of an amplification technique. A typical example is that described by Self,[47] in which the alkaline phosphatase label is employed with nicotinamide adenine dinucleotide phosphate (NADP) as substrate; the product nicotinamide adenine dinucleotide (NAD) is then used as the coenzyme in a secondary reaction with alcohol dehydrogenase, the NADH produced being detected with a tetrazolium dye reaction, the NAD being recycled. A similar approach has been described by Obzansky et al. in which phosphorylated flavin adenine dinucleotide (FAD) is split by alkaline phosphatase, the cofactor activating the apoenzyme D-amino acid oxidase, which then acts on proline to release hydrogen peroxide.[48]

4.2.6 Relative Detection Limits

It is difficult to make accurate comparisons between the relative detection limits of the various substrates that can be used, because they have all been described in different analytical systems incorporating other variables. However, an attempt is made in Table 2 to compare

Table 2 Comparison of the detection limits for immunometric assays of thyroid stimulating hormone (TSH) employing alkaline phosphatase as the label. Detection limit expressed as two standard deviations above the zero standard signal [data extracted by permission from Bronstein et al.[44]]

Detection reaction	Detection limit (TSH mIU L^{-1})
Nitrophenol/absorbance	0.02
NADP/amplification/absorbance	0.024
Luminol/luminescence	0.06
Terbium chelate/fluorescence	0.003
AMPPD/luminescence	0.0045

AMPPD, 3-(2′-spiroadamantane)-4-methoxy-4-(3″-phosphoryloxy)-phenyl-1,2-dioxetane.

performances using the enzyme label alkaline phosphatase in an immunometric assay format.

4.3 Fluorophores

The choice of fluorophore label will depend on the quantum yield, the separation between the emission and excitation wavelength peaks (Stokes shift) and the potential quenching effects which may result from the conjugation procedure or from any endogenous substances in the sample or reaction mixture; the latter will be particularly important in the case of a homogeneous immunoassay format. Fluorophores with the highest quantum yield include phycobiliprotein, fluorescein, and rhodamine derivatives; other molecules that have been used include umbelliferone derivatives and Lucifer Yellow.[49] The fluorophores are conjugated to the antigen or antibody depending on the type of assay using conventional techniques, usually with the aid of a small linker molecule in the case of hapten molecules.

The limitations of quantum yield, background fluorescence, and quenching have been overcome by the development of time-resolved fluorescence probes. The fluorescent molecules employed in this technique have longer decay times than conventional fluorophores, such as fluorescein and endogenous fluorophores in biological samples (60–100 μs compared with 5–100 ns). Thus if such a fluorophore is excited the emission decays more slowly such that, by delaying the collection of light emitted, any endogenous interfering fluorescence can be excluded.[50] In the applications to quantitative immunoassay this property is linked to pulsed excitation using a laser light source in such a way that amplification of the signal is achieved by the use of multiple excitation/emission cycles. The longer decay times are exhibited by the lanthanide chelates such as europium (^{37}Eu), samarium (^{37}Sm) and terbium (^{37}Tb) coupled with organic ligands, such as β-naphthyltrifluoroacetone, pivaloytrifluoroacetone, and benzoyltrifluoroacetone. The most common application described has been for dissociation-enhanced lanthanide fluorescence immunoassay (DELFIA), in which the antigen or antibody is labeled with a europium chelate, the europium exhibiting only weak fluorescence in this state.[51] On completion of the immunochemical reaction the europium is released from the hydrophilic chelation with the use of a highly lipophilic environment containing a β-diketone chelator, enhancing the fluorescence of the europium ion. The use of alternative lanthanide ions enables more than one assay to be performed in a single tube.

4.4 Luminescence

Luminescence reactions are generally divided into chemi- and bioluminescent reactions, the former depending on a chemical reaction and the latter the result of an enzyme-mediated reaction. The light emitted from such reactions is collected on a photomultiplier tube. The most commonly employed molecules in chemiluminescent reactions are luminol, acridinium esters, adamantyldioxetanes, and oxalate esters. As indicated earlier, some of these luminescent species have been incorporated in enzyme substrates. The oxidation of the molecules with hydrogen peroxide leads to the creation of an excited-state decay, leading to the release of light.[45,52,53]

The most commonly used bioluminescent reactions employ either firefly luciferase which catalyzes the oxidation of luciferin requiring adenosine triphosphate (ATP), or a bacterial luciferase which catalyzes the oxidation of a long-chain aldehyde requiring NADH and an oxidoreductase. In most immunoassay applications of bioluminescence the enzyme has been employed as the label.[54]

There have been a number of calcium-dependent photoproteins described in which the luminescent emission is triggered by the presence of calcium. The most commonly used of these photoproteins are the aquourin, and recombinant engineered forms of these proteins have been developed to facilitate large-scale production.[55]

The most recent addition to the family of luminescent reactions harnessed for immunoassay has been electrochemiluminescence. In one example the ruthenium(II) tris(bipyridyl) ion $Ru(bpy)_3^{2+}$ (employed as the covalently coupled label) is oxidized at the surface of an electrode forming the strong oxidant $Ru(bpy)_3^{3+}$. At the same time tripropylamine (TPA) which is present in excess in solution is oxidized at the electrode to form the cation radical $TPA^{\bullet+}$, which spontaneously loses a proton to form the radical $TPA^{\bullet}$. The two species react to form the excited state of the ruthenium complex – the energy derived from the large difference in electrochemical potentials of the two species. The excited-state ruthenium complex decays, emitting light at 620 nm. The

ruthenium compound returns to its original state ready to be oxidized again and re-enter the cycle.[56] Alternative electrochemiluminescence systems and a wide range of applications have also been described.[57]

4.5 Substrate/Inhibitors/Enhancers

It is obvious that in a two- or multicomponent reaction it is possible to consider any one of the components as a label, given that it can be coupled to the antigen or antibody without compromising the unique binding properties of either. Indeed, one of the components may be more suited to the production of a conjugate, e.g. substrates linked to haptens. However, in addition, the complementarity of two reactants has been exploited in a range of immunoassays, in particular those using a homogeneous format.

In addition to conventional enzyme or substrate labels the use of inhibitors and cofactors as labels has also been described, e.g. the use of a phosphonate as a label which inhibits the enzyme acetylcholinesterase[58] and FAD and apoglucose oxidase.[48,59]

4.6 Particles and Metal Sols

The incorporation of particles into an immunoprecipitate and the accumulation of particles (without agglutination) have been used for the detection and/or quantitation of antigens (and antibodies). One of the first particles used as a label was the erythrocyte, taking advantage of the size and color to demonstrate the presence of antigen using labeled antibodies.[60] In more recent years latex particles have become the particle of choice.[61] The quantitation of antigens (or antibodies) has been described using turbidimetric or nephelometric detection of the immunoaggregate formed (see later description), the presence of the particle allowing the production of a multivalent antigen either to facilitate the design of the competitive assay for haptens or to increase the sensitivity of an immunoagglutination reaction. In the majority of turbidimetric and nephelometric assays, particles in the size range 40–200 nm are employed, although larger species are also used, particularly when using a near-infrared light source for nephelometric detection. The use of carbon, silver, and gold sols has been described, although methods are mainly confined to assays for urine analytes because the sols appear to suffer nonspecific protein adsorption from serum samples.[62]

The use of colored latex particles, typically blue, and metal sols, has become extremely popular for labeling of immunoreagents employed in lateral flow, liquidic circuit, and immunochromatographic disposable devices. These methods depend on the visibility of the concentrated latex particles at the site of capture of antigen by a covalently bound antibody (see later discussion).

5 RECOGNITION AND CHARACTERIZATION

Antibodies are an important part of the armamentarium of the diagnostician in the recognition of proteins and other macromolecules, including cells. Similarly, an antigen molecule is vital to the recognition of the presence of specific antibodies. The use of the antibody reaction is usually complementary to some form of separation technique.

5.1 Immunoelectrophoresis

One of the earliest techniques for characterizing a mixture of antigens of interest in a solution, such as serum or urine, was immunoelectrophoresis performed in a thin agarose film. The technique involves the electrophoresis of sample from a cylindrical well parallel to a narrow trough cut in the gel; a single gel may comprise several sample wells and troughs. In the process of electrophoresis, the proteins are separated according to their electrophoretic mobility. After electrophoresis, antiserum against the protein(s) of interest is placed in the trough. Diffusion of antigen from the original electrophoresis track and antibody from the trough will led to the formation of a precipitin arc when the antigen is present. If a general polyclonal antiserum is used (i.e. raised against a range of antigens), then a series of arcs will form, the mobility of the original sample analyte giving an idea of the identity of the antigen causing arc formation.[63]

An alternative approach, termed two-dimensional immunoelectrophoresis, has been employed to obtain a higher resolution of mixtures of proteins. In this technique the sample is again electrophoresed into an agarose gel from a cylindrical well. The gel track in which the electrophoresis has taken place is then cut out and butted against a second square agarose gel containing antibody or a mixture of antibodies. Electrophoresis is performed into this second gel and at 90° to the dimension of the first electrophoresis cycle. Immunoprecipitation occurs at the position of equivalence for each antigen (see later discussions on immunoprecipitation reactions); the height of the precipitin peak will give an indication of the amount of antigen present in the sample. When using a single antibody reagent in the second gel, the technique is particularly useful for detecting variants, fragments, or complexes of the antigen of interest.[64]

5.2 Immunofixation

This technique has replaced immunoelectrophoresis as the method for detection of individual proteins, such as paraproteins, in serum or urine from patients with myeloma. Electrophoresis is performed in an agarose

Figure 2 Results from an immunofixation of a patient's serum sample containing a paraprotein subsequently shown to be an immunoglobulin M kappa.

gel film. The film is then covered with a layer of antiserum containing antibodies against the protein of interest, usually in the form of an impregnated strip of cellulose acetate. The antibodies diffuse into the agarose gel forming an immunoprecipitate; the unreacted proteins can then be washed out of the gel and the immunoprecipitate visualized with a protein stain. An example is illustrated in Figure 2.

5.3 Western Blotting

This technique extends the use of immunoblotting to other separation matrices and does not depend upon the formation of an immunoprecipitate. It is used particularly with polyacrylamide gel matrices and permits the detection of much lower concentrations of protein. The technique depends on the transfer of the proteins at the completion of the electrophoretic step from the gel, with immobilization on to a nitrocellulose or nylon membrane. The transfer is commonly achieved by electrophoresis, trapping the gel and nylon membranes between buffer-wetted filter paper. After capture of the proteins on the membrane they can be detected using labeled antibody probes; typical labels include horseradish peroxidase with calorimetric or luminescence detection, or gold sols. The label may be attached to an antispecies second antibody as a more generic reagent which can be used with a reagent of primary detection antibodies.

This immunoblotting technique can be used to detect a single protein (or epitope) following separation according to molecular weight, size, and charge or isoelectric point. The technique can be used for epitope mapping, structural domain analysis, and ligand binding studies as well as then providing the material for antibody production or amino acid analysis and protein sequencing.[65]

The detection limit of this technique is between 100 and 1000 times lower than that using immunofixation, with a limit of detection of 10 pg quoted for colorimetric staining and 1 pg or less claimed for luminescence, gold sol, and radioisotope labeling.[66]

5.4 Immunocytochemistry

Labeled antibody probes have been used for many years in the study of the viability, morphology, and lineage of cells. The technique has been applied to biopsy material, to blood and bone marrow cells, and to microbiological organisms. The critical first step in any cytochemical application is the preservation of the cellular morphology, many of the conventional tissue-processing techniques incorporating extreme conditions that may destroy the structure of the epitopes of interest. Fixation can be achieved in paraffin or acrylic blocks whilst maintaining antigenicity, whilst cryofixation techniques have also been described.[67]

Antibody probes can either be labeled directly or with a second labeled antispecies antibody. The most commonly used labels are enzymes such as horseradish peroxidase, alkaline phosphatase, and gold sols. Fluorescent labels are not commonly used because of the autofluorescence of the sample. The enzyme labels produce a permanent record and for electron microscopy can produce the density of product required; gold sols are particularly useful for electron microscopic examination.[68]

One of the critical issues both for the preparation of the sample and for the choice of reagent is the penetration of the antibody probe. Excessive labeling can produce an extremely large immunoreagent complex that will limit the sensitivity of detection. The use of an antibody fragment with a sensitive signal reaction may help to increase penetration and lower detection limits.

5.5 Flow Cytometry

The technique combines the light-scattering properties to determine the size and granularity of cells together with the attachment of fluorescent-labeled antibody probes to give further differentiation to the cell types, as well as the detection of specific antigens. It is also possible to assess the membrane potential, pH, enzyme activity, and DNA content of the cells.[69]

The basic design of the flow cytometer involves a means of projecting a stream of cells through a flow cell that is illuminated by a laser light source. The cells enter the flow cell under pressure through a small aperture which is surrounded by a sheath fluid. The sheath fluid creates a hydrodynamic focusing effect and draws the sample into

a stream; careful optimization of sample and sheath fluids ensures that the cells pass singly through the detection zone.

Light scattered in the forward angle (which is proportional to the radius of a sphere) provides information on the size of the cell, whilst the light scattered at 90° (proportional to the refractive index of the cell) provides information on the granularity of the cell.

Fluorescence emitted from suitable probes covalently coupled to specific antibodies that have reacted with their complementary antigen is detected at 90°. Selection of light scattering and fluorescence is usually achieved by the use of appropriate filters.

The third component of the flow cytometer is the computer which collects the light scattering and fluorescence data and manipulates them according to established algorithms, providing a wide range of parameters with respect to type and number of cells present in a given sample population.

The advent of monoclonal antibodies led to the creation of a library of antibodies directed against cellular antigens. These antibodies have been grouped into clusters based on their cellular reactivity, and termed a cluster of differentiation (CD). Considerable research effort has been focused on the clinical application of the study of cellular antigens.[70]

Whilst the initial application of flow cytometry was in the field of differentiation of white blood cells, the unique capabilities of the instrumentation to differentiate a mixed population of fluorescently labeled particles have led to the description of its use for multianalyte immunoassays using fluorescent-dye-labeled latex particles. In one configuration, differential dyeing of identically sized particles with two different dyes, with emissions at two different wavelengths, allows the recognition of aggregates and permits the discrimination of at least 64 different sets of particles. In fact, three fluorescent dyes are used, orange and red for classification of the particles and green for analyte measurement.[71]

5.5.1 Cell Sorting

Cell sorting is an important adjunct to the diagnostic capabilities of flow cytometry. It is achieved by employing one of two different techniques. The first utilizes the change in direction of flow of individual cells by electromechanical means. As the technique does not require passing cells through a narrow orifice, fragile and large cells and aggregates can be separated successfully. The second technique involves the packing of cells, after analysis, into tiny droplets, charging the droplets that contain cells and then deflecting these droplets in an electrical field. The former technique can sort about 10^3 particles per second whilst the latter can accommodate about 10^4 particles per second.

5.6 Immunosensors

The requirement to label one component of the antigen–antibody reaction, and in many cases to "develop" or visualize that label, had introduced complexity in the use of the reaction and made interrogation of the reaction kinetics both difficult and in many instances unreliable. The advent of the immunosensor therefore allowed real-time or kinetic analysis of the antigen–antibody reaction.[13,14]

An immunosensor is a form of biosensor in which the biorecognition molecule is an antibody (or antigen in the case of the detection of an antibody) which is directly coupled to a transducer that detects the binding event and converts it into an electronic signal. A wide range of examples have been described including those detecting the binding directly whilst others employ detection of a label. The direct detection of binding can potentially be achieved by the change in electrochemical characteristics (potential, current, conductance), heat released (calorimetry), mass, or refractive index. It is beyond the scope of this article to describe all of the principles[72] and further discussion will therefore be limited to those that have been commercialized and are in routine use.

The greatest success in immunosensors has been achieved with optical sensors which employ the phenomenon of the evanescent wave. There are several different approaches to detection including surface plasmon resonance, employing a thin gold film on the sensor surface,[73] a resonant mirror approach with high and low refractive films on the surface of a prism,[74] and waveguiding material in combination with a diffraction grating.[75] The surfaces are coated with a dextran layer or some other means of limiting nonspecific binding whilst also providing a means of coupling the antibody (or antigen) to the surface.

The sensor techniques measure the proximity of higher-molecular-weight species close to the surface, and consequently reflect the specific binding interaction (assuming that nonspecific binding to the surface has been negated). A signal will be produced due to the presence of the species of interest, and other high-molecular-weight species in the medium (the bulk effect) which will contribute a signal and must be discounted; the bulk effect is seen as a rapid increase in signal which remains constant (Figure 3). The true binding is obtained after subtraction of the bulk effect signal, and is proportional to the mass of bound analyte. The rate of binding will also be determined by the speed with which the species of interest approaches the surface of the sensor; rapid binding will deplete the local concentration and thus influence the progress of the binding curve. This can be overcome by stirring the mixture or flowing

Figure 3 Response observed for a surface plasmon resonance optical sensor to demonstrate the bulk effect response on addition of buffer 2 to a surface on which had been covalently coupled a monoclonal antibody against β_2-microglobulin followed by addition of antigen in buffer 2. The response is expressed as relative to the baseline established with buffer 1.

the sample over the sensor surface; failure to do this will introduce a mass-transfer effect on the binding characteristics.

The real-time monitoring of the association and, by removal of the sample and replacement with buffer, dissociation will enable the characteristics of the antigen–antibody reaction to be determined and thus the binding characteristics of antibodies to be compared. The technique can also be used for epitope mapping and for the quantitation of both low- and high-molecular-weight analytes; in the case of a low-molecular-weight analyte a competitive technique has to be used with a high-molecular-weight multivalent analyte complex being created (e.g. coupling hapten molecules to a latex particle or gold particle core).[76]

6 QUANTITATION

It is clear that several of the techniques already described can be used for semi- and full quantitation of the species of interest. In some situations a qualitative answer is all that is required but it should be noted that in many cases a strict cutoff between negative and positive results is required and therefore the rigor of analytical performance required is the same as for a quantitative assay.

There are many different analytical approaches to quantitative immunoassays that would be impossible to encompass in a short review. The following discussion will therefore be limited to the quantitation of antigen; however, the reader interested in the detection of antibodies will readily be able to reconfigure the sequence and choice of reagents for his or her needs. In certain examples the antigen may have a unique property which either negates the need for additional immunoreagents and makes use of other properties, such as enzyme activity, as in the case of an immunocapture assay for bone alkaline phosphatase,[77] or binding to an alternative affinity ligand (e.g. a lectin).

6.1 Heterogeneous Immunoassays

The basic requirement for any quantitative immunoassay is the differentiation between bound and unbound (unreacted) species. The two basic assay designs embodied in the heterogeneous format are those of competitive and noncompetitive immunoassay.

6.1.1 Competitive Immunoassay

In the predominant example of this format, labeled antigen competes with the sample antigen for a limited number of antibody binding sites. The antibody molecules are immobilized on a solid phase which permits the separation of bound and free labeled antigen; the amount of bound labeled antigen is then measured according to the properties of the label and the amount of sample antigen is quantified by comparison of the signal with that obtained from a calibration curve. A schematic of the assay principle and the relationship between bound label and sample analyte concentration are depicted in Figure 4(a) and (b). The addition of sample and labeled analyte can be performed simultaneously or sequentially, the latter offering a 2–4-fold improvement in the detection limit. An alternative approach for quantitation of a hapten would be to couple a limited amount of

Figure 4 (a) Schematic diagram of a heterogeneous competitive immunoassay employing an immobilized antibody (Y) with labeled antigen (✶◆) and sample antigen (◆) competing for binding sites. (b) A typical response curve.

antigen to the solid phase and then use a labeled antibody with competition of sample analyte with the immobilized antigen. The bound antibody could alternatively be quantitated with a labeled second antispecies antibody.

The optimization of reactant conditions will depend on the concentration range of analyte in the sample and the equilibrium (affinity) constant of the antibody. Assays requiring higher levels of sensitivity require antibodies with higher affinity constants. Several optimization strategies have been developed with assessment being based on the precision profile (coefficient of variation of duplicates plotted against analyte concentration) which gives a practical demonstration of the analytical range of the assay.[78] In broad terms, greater sensitivity is achieved at a lower concentration of antibody whilst better precision is achieved at a higher concentration.

The competitive form of assay is applicable to an analyte where the concentration range is either relatively narrow (i.e. where good discrimination is required over a narrow concentration range) and/or where the sample concentration range may be very large and where the hook effect in the immunometric assay could be a problem (see the next section); this is exemplified in the case of an assay for albumin in urine used for the early detection of diabetic nephropathy but where a sample with a very high level may also be encountered, as in the case of nephrotic syndrome.[79] The competitive format employs a limited amount of antibody, especially when seeking higher sensitivity, and therefore the addition of an accurately defined amount of antibody reagent is critical to the reproducible performance of the assay. Finally, the competitive assay format may be the only option for the quantitation of small molecules (haptens) which effectively possess only a single epitope.

6.1.2 Immunometric Assay

In the case of larger molecules which possess more than one discrete epitope region, it is possible to employ an immunometric or sandwich format. An antibody coupled to a solid phase is employed to capture the analyte of interest, the captured antigen then being detected with a second labeled antibody. Whilst this technique was first described in the late 1960s,[80] it has become more popular with the advent of monoclonal antibodies capable of providing binding pairs that recognize different epitope regions of the antigen.

The addition of sample analyte and labeled second antibody can be undertaken simultaneously or sequentially. In the former case there is a risk, at very high concentrations of antigen, of the analyte saturating both capture and second antibodies, producing the so-called ''hook effect'', after which point the assay response falls at higher analyte concentrations, effectively as a consequence of the failure to form ''sandwich complexes'' and

Figure 5 (a) Schematic diagram of a heterogeneous immunometric assay employing an immobilized first antibody (Y), sample analyte (◆), and labeled second antibody (Y*). (b) A typical response curve.

thereby giving a falsely low result. This effect can be overcome by using a sequential approach and by ensuring there are sufficient amounts of capture and second (detector) antibody available; the alternative is to employ a competitive format. The format of the immunometric assay and a typical calibration curve are shown in Figure 5(a) and (b). The sensitivity of the immunometric format can be enhanced by the choice of the label: the amount of signal increasing in proportion to the amount of analyte present. However, a limitation on sensitivity, as in the case of all immunoassays, is the level of nonspecific binding, and it is important to minimize this effect as much as possible.

Whilst the competitive format is required for most hapten assays, the option of the immunometric approach has been demonstrated with the use of anti-idiotypic antibodies.[81,82]

6.1.3 Separation Methods

The quality of the separation of bound from free label is vital to the performance of an immunoassay, being a major influence on the nonspecific binding component of the response. The solid phase must therefore be capable of rapid separation and effective washing to remove nonimmunochemically bound labeled reactant. It goes without saying that the antibody must have a sufficiently high affinity constant for the antigen to ensure that the immunocomplex is not disrupted during the washing stage. The solid phase should also ideally have a large surface area to ensure minimization of diffusion distances, whilst in the case of the immunometric assay enabling a high concentration of capture antibody to be achieved. However, it is also important to ensure that the possible adsorption of labeled reactants is minimized by blocking of any ''bare'' surface of the solid phase.

Early separation methods were based on the use of protein precipitation techniques, e.g. poly(ethylene glycol)

or ammonium sulfate, the immunochemical reactants all being in "free" solution. Alternative separation techniques have also been described, including electrophoresis, gel filtration and ion-exchange chromatography.

However, today the majority of separation methods are based on the use of antibodies (or antigens) either adsorbed or covalently coupled to a solid phase. The choice of solid-phase matrix may depend on the equipment available in the laboratory, but comprises the inside surface of a tube or microtiter plate well, plastic beads, paddles, porous disks or magnetizable particles. Reaction tubes offer the lowest surface area available, followed by microtiter plate wells and large plastic beads, whilst small beads (e.g. latex particles) and magnetizable particles offer the largest surface areas;[83] the latter can also offer the shortest diffusion distances. The porous disk approach, with disks made from several materials including chromatography paper, has been extremely popular in disposable immunoassay devices (see later discussion).

In some cases another binding protein has been coupled to the solid phase; this can provide a universal solid-phase reagent which can then be employed with a range of immunoassays. This reagent may be an antispecies antibody or protein A.[84] An alternative which also provides opportunities for signal amplification is to use one of the biotin–avidin or biotin–streptavidin pair, the other being coupled to the reagent which is intended to be the primary reagent attached to the solid phase.[85]

6.2 Homogeneous Immunoassays

As the name implies, the homogeneous immunoassay does not require a separation step, the delineation between the free and bound fraction being achieved by modulation of a property of one of the reactants by the antigen–antibody binding reaction. Thus in the context of the earlier discussion the immunosensor systems described could be considered as homogeneous immunoassays. However, there have been a range of free-solution homogeneous immunoassays described, with many being commercialized very successfully.

6.2.1 Light Scattering Immunoassay

One of the first examples was the use of the immunoprecipitation reaction for the quantitation of specific proteins. The principle, described in Figure 6(a–c), is based on antibody molecules binding first to one protein antigen molecule to form a dimer and then to a second antigen, thereby forming a complex which increases in size, and ultimately forming an immunoprecipitate. As the complex forms there is an increase in the light scattering which can be measured either turbidimetrically or nephelometrically (utilizing right- or forward-angle scatter, the latter giving better sensitivity for larger complexes). The majority of methods described employ a polyclonal antiserum with the opportunity of more epitopes available for binding, although mixtures of monoclonal antibodies have been used. The rate of immunoprecipitate formation is usually enhanced by the inclusion of a polymer, typically poly(ethylene glycol) 6000.[86]

Figure 6 Various configurations for light scattering assays in which direct agglutination (a) can be employed with (Y) or without (Y) the use of a latex particle-labeled antibody; (b) inhibition of agglutination by a small sample analyte; (c) an inhibition assay with both reactants labeled with particles.

The applicability of this approach has been greatly enhanced by the use of latex particles either to enhance the amount of light scattering or to act as a core for the production of a multivalent hapten molecule which extends the use of the light scattering assays to small

molecules in addition to avoiding the ''hook effect'' by analogy with the competitive assay format described earlier. The particle size employed has ranged from 40 to over 500 nm; the smaller particles, however, provide more surface area and will remain in suspension.[87] The choice of particle may be determined by the coupling chemistry for attachment of the antibody (or antigen in the case of a competitive assay); many examples of latex-labeled assays have, however, depended on adsorption without any obvious deleterious effects.

An alternative approach to turbidimetry and nephelometry when using a latex particle-labeled assay employs particle counting, which has been shown to achieve lower detectable levels and also permits the quantitation of polypeptide hormones and other proteins not measured by the conventional light scattering techniques.[88]

6.2.2 *Enzyme-labeled Immunoassay*

The enzyme multiplied immunoassay technique (EMIT®) is a competitive technique in which the antigen, typically hapten (although an application for proteins has been described), is coupled to an enzyme in such a way that binding to the antibody results in inhibition or activation of the activity.[89] The main enzymes used have been lysozyme, malate dehydrogenase, and glucose-6-phosphate dehydrogenase, with the latter being the most commonly described in a range of commercial assays for drugs. A schematic diagram illustrating the principle of the method is shown in Figure 7(a) and (b).

Figure 7 Schematic diagram of a homogeneous enzyme immunoassay which in (a) shows that the active site of the enzyme linked to hapten (→) is blocked by the addition of antibody (≻). In the presence of sample analyte (ii) there is competition for antibody and the antibody binds to hapten enzyme conjugate such that activity is present leading to breakdown of substrate (→). In the case of a substrate-(or inhibitor)-labeled assay (b) the enzyme is employed as the reagent with access of the labeled hapten limited upon binding of antibody.

Subsequently both substrate and cofactor labeled techniques were described, the basic principle being similar in that coupling of substrate (or cofactor) to enzyme was inhibited by the proximity of antibody binding to the labeled antigen. In one example FAD was employed as the label, with the apoenzyme of glucose oxidase employed as a reagent.[59]

Cloned enzyme donor immunoassay (CEDIA®) employs recombinant DNA technology to produce new strains of *E. coli* synthesizing inactive forms of the tetrameric enzyme β-galactosidase. These fragments comprise a protein of approximate molecular weight 113 000 Da, called the acceptor protein, and a small polypeptide (of approximately 90 amino acid residues), called the donor polypeptide. Association of the acceptor and donor fragments has been shown to form monomer which can then aggregate to form active β-galactosidase. Hapten coupled to the donor polypeptide does not impair the formation of monomer and thus generation of enzyme activity; however, antibody bound to the hapten inhibits monomer formation. This competition of sample analyte (or hapten) for antibody binding sites results in more donor polypeptide-labeled hapten being available to form monomer with acceptor protein and thence enzyme activity.[90]

6.2.3 *Fluorophore-labeled Immunoassays*

The most commonly used homogeneous fluorescence immunoassay employs a polarized excitation light source. If a polarized light source is used to excite the fluorophore molecules, the energy is absorbed more efficiently by molecules whose oscillating dipoles are parallel to the plane of the polarized light. Furthermore, the degree of polarization of the emitted light is dependent on the lifetime of the excited state and the rotational motion of the molecule. All molecules in solution are in a constant state of motion (Brownian motion) which is dependent on their size and shape as well as solvent viscosity and temperature.

Thus a fluorophore coupled to a hapten molecule will exhibit greater Brownian motion when free in solution than when the hapten fluorophore complex is coupled to its complementary antibody. The rotational time of the immuno complex will be about 10–100 ns compared with 1 ns in the case of the fluorophore–hapten molecule. Experience has shown that the antigen needs to be less than 20 000 Da in order to detect the change in polarization; furthermore, the fluorescence lifetime of the fluorophore must be greater than the rotational time of the labeled antigen (hapten) and fluorescein, with a lifetime of 4.5 ns, has been one of the most

successful labels used. The degree of polarization of the fluorophore hapten which is inversely proportional to the concentration of the sample analyte is measured in the most commonly used application of this technique.[91] The main limitation of the method is the effect of serum proteins, and a high dilution of sample is required, which limits the sensitivity of the assays.[92]

The energy emitted by a fluorophore may be influenced by many factors, including the close proximity of energy-donating or energy-accepting groups. Examples have been described of direct quenching of the fluorophore-labeled antigen upon binding of the antibody.[93] An alternative approach, termed fluorescence excitation transfer immunoassay (FETI), involves the labeling of antigen with fluorophore and the labeling of antibody with an energy-accepting (or -quenching) molecule. When labeled antigen binds to antibody the fluorescence emission energy of the antigen label excites the antibody label, itself therefore being quenched. The transfer of energy requires the wavelength of emission of the first molecule to match that of the excitation of the second and the close proximity of the two molecules (approximately 10 nm or less) because the rate of transfer is inversely proportional to the sixth power of the distance between the molecules.[94] The approach was first described using fluorescein as the donor and rhodamine as the acceptor molecule.

The method effectively extends the Stokes shift, although in most applications the quenching of the donor molecule is usually measured rather than the excitation of the donor.[95] A number of alternative fluorophore pairs have been described and methods have been reported for both hapten and protein antigens. A schematic diagram illustrating the principle of the assay is shown in Figure 8.

Figure 8 Diagrammatic representation of a FETI in which the proximity of fluorophore-labeled antigen (^{F1}) to fluorophore-labeled antibody (^{F2}) leads to excitation of F2 by emission of F1; the presence of sample analyte (◆) blocks excitation transfer.

A number of energy-enhanced and energy-transfer luminescence immunoassays have also been described, although none has been commercialized to date; all are based on the interaction between two molecules in close proximity.[96,97] In one configuration recently described, a luminescent oxygen channeling assay (LOCI™),[97] the assay depends on the proximity of two particles. A photosensitive compound is dissolved in one particle which upon exposure to light produces singlet oxygen. The second particle species contains an olefin which reacts with the singlet oxygen to produce a chemiluminescent emission. This reaction only takes place when the particles are brought together as a pair. Haptens are measured using competition of sample with hapten and antibody-labeled particles – photosensitive molecule and olefin containing, respectively. In the case of macromolecular antigens one antibody is coupled to the olefin-containing particles; the photosensitive particle is coupled to streptavidin, which is subsequently bound to the initial antibody complex with the aid of a biotin-labeled second antibody. This homogeneous format was demonstrated for thyrotropin and other macromolecules.[97]

7 MICROFABRICATION AND ENCAPSULATION

An important development in the field of immunoassay technology has been the encapsulation of, initially some and now all, of the reaction components of the quantitative immunoassay into a device that enables the technology to be used by operators with little or no technical training. This development has been achieved through the successful combination of several technologies, including liquid handling, printing, porous matrices, and plastic moulding. The innovation today is now moving toward miniaturization of devices, hence microfabrication technologies with the additional benefits associated with miniaturized devices, e.g. rapidity of response, portability of device, and economy of manufacture, are being exploited.

7.1 Disposable Reaction Cells

These devices typically comprise plastic cuvettes with several compartments that contain the reagents necessary for the reaction, channels to facilitate mixing, an entry port for the sample, and a compartment, where the reactants are mixed, that forms the optical cell. An example is the Bayer DCA 2000® (Bayer, Tarrytown, NY, USA) for the measurement of HbA_{1C} in which the reagents for the immunoassay comprise latex particles to which are coupled peptide molecules that have been used as the

immunogen to produce a monoclonal antibody that recognizes the HbA_{1C}. Mixing of these two reagents leads to the formation of a light-scattering aggregate. The addition of sample HbA_{1C} will inhibit the amount of aggregate formation (a competitive light-scattering assay). The cartridge also contains reagents to hemolyze the erythrocytes, necessary for the immunoassay, and for quantitation of the total hemoglobin to enable the percentage of glycated hemoglobin (HbA_{1C}) to be calculated.[98]

In another configuration, the same manufacturer has adapted the same cassette format for the quantitation of albumin in urine by a direct agglutination reaction. In this instance the cassette also contains reagents for the quantitation of creatinine so as to allow calculation of the albumin : creatinine ratio. An alternative configuration has been produced by another manufacturer for the measurement of drugs, such as theophylline. In this case the measurement of hemoglobin is used to correct for the hematocrit of the sample.[99]

7.2 Flow-through Cells

A very simple device that employs a porous matrix to which an antibody is coupled to provide a capture solid phase has been described for several analytes and for which a number of variants are available.[100] The assay format is usually employed for high-molecular-weight analytes. Addition of sample to the porous matrix pad leads to capture of the antigen; addition of a second labeled antibody results in the formation of a sandwich. If the antibody is labeled with colored latex or gold sol particles the presence of antigen is immediately evident. Alternatively, if the label requires visualization, e.g. an enzyme requiring substrate, then another reagent is added. The porous matrix is usually attached to an absorbent reservoir to collect excess liquid, and washing steps are included to improve discrimination at low analyte concentrations.

This type of device is a sophisticated form of the dot blot that is used in many research laboratories to detect the presence of antigen or antibody species and may be considered as a variation of the immunofixation principle described earlier. A diagrammatic representation is shown in Figure 9.

7.3 Lateral Flow Devices

An alternative approach to the reactants (and solvent) flowing through a porous matrix is to employ the porous matrix as the total reaction cell by flowing reactants along the device, allowing the separation of free and bound labeled antigen or antibody within the confines of the porous matrix. These devices have been given a variety of names, including lateral flow devices – often also called stick tests because of their apparent simplicity.

Figure 9 Schematic diagram of a flow-through device with analyte of interest (◆) captured by an immobilized antibody (Y) and detected with a second antibody (Y) labeled with either colored particles or enzymes.

In its simplest configuration, the lateral flow device comprises a porous matrix, often a type of chromatography paper which at one end, the sample addition zone, an amount of labeled antibody reagent (in the case of an immunometric assay for a large antigen) is deposited (dried down). Further along the matrix a defined amount of capture antibody is covalently coupled. At the farther end from the sample addition zone, an antispecies antibody is covalently coupled to the matrix. The sample when added dissolves the first labeled antibody reagent which binds to any antigen present and migrates along the strip of matrix until captured by the immobilized antibody. The excess of labeled antibody migrates further until captured by the antispecies antibody providing proof of migration (an internal quality control check). The first antibody is usually labeled with color latex particles or gold sol particles to visualize the sandwich, indicating the presence of antigen.[101]

It is also possible to configure the assay with labeled antigen in order to detect a small molecule. The principle of both assays is depicted in Figure 10. The ratio of the antigen and antibody reagents in the competitive style of assay is critical to the cutoff value that determines a negative from a positive result in most of the configurations of this type of assay.[102] It is possible for the flow-through and lateral flow devices to achieve quantitation with the aid of a reflectance meter. The type of assay can also be configured to detect more than one

Figure 10 Schematic diagram of a lateral flow device in which a sample (◆) added to zone 1 dissolves the detector antibody (•—<), the complex migrating until captured in zone 2. Excess labeled antibody is captured in zone 3.

analyte in the same sample by immobilizing more than one antibody specificity, in a series of discrete bands, together with the appropriate mixture of reactants at the sample application area.[103] In addition, more complex configurations can be achieved by the design of liquidic circuits which can be used to delay the mixing sequence of reactants.[104]

The flow-through approach can also be used to produce an analog signal such that quantitation is achieved without the need for a reader (i.e. similar to a thermometer output), termed an immunochromatographic device. In one configuration the analyte binds to labeled antibody at the application zone and this complex migrates along a porous matrix to which capture antibody is immobilized. The distance of migration is proportional to the amount of antigen, i.e. until all of the antigen has been captured.[105]

A critical feature of the flow-through and lateral flow devices is the choice of the porous matrix. Much of this intellectual property is either closely guarded in the patent literature or not disclosed at all, with few papers describing the development of this technology. However, it is clear that the surface charge on the matrix, as is the case for all solid surfaces, e.g. latex particles, plays an important role, as do the surface tension properties and the ionic species of the solvent. The porous matrix is particularly critical when the whole blood provides the solvent for solution of reactants and the mobile phase.

7.4 Miniaturization of Devices

The miniaturization of immunochemical reactions has a number of benefits, including reduction in diffusion distances, thereby increasing the rates of reaction, and reduction in the reagent requirements. The technology takes advantage of modern microfabrication techniques that enable large numbers of devices to be produced with high levels of accuracy of manufacture. Such microfabrication has permitted the machining of narrow channels in materials such as silicon chips, glass, and chromes and the construction of valves and pumps.[106] There are several examples in the literature where small numbers of micromachined devices have been produced for encapsulating an element of the antigen–antibody reactions for quantitation of an antigen. Thus capillary electrophoresis has been employed to provide the separation in a cortisol assay with a 30-s reaction time.[107] A latex agglutination assay with fluorescent-labeled beads has been described for a protein in a reaction cell etched in Pyrex glass. An alternating current was employed to enhance the rate of agglutination, the end-point being monitored with a fluorescence microscope and image analyzer; the reaction volume employed was 0.4 μL.[108]

8 APPLICATIONS

Immunochemical techniques now dominate the analytical methods in the biological sciences and in particular in the application to diagnostic techniques in medicine. It would be impossible to document all of the applications, qualitative or quantitative, that have been described, and therefore the discussion will be limited to providing an overview of the limits of detection of the methods described, some comments on the accuracy and precision of methods, and then some specific examples of method performance. The range of analytes that can be measured by immunoassay and the applicability of the techniques described in this article are illustrated in Figure 11.

8.1 Calibration and Quality Assurance

It will be clear from the earlier discussion that the immunogen plays an important role in determining the specificity of the antibodies produced. Differences between the immunogen and the analyte of interest either inherent or produced during purification (and conjugation in terms of a hapten) can result in unsatisfactory antibody reagents; similarly, differences in the nature of the calibration material antigen can compromise the accuracy of an assay. However, probably the greatest influence on the accuracy of an immunoassay is the incorrect assignment of the analyte value to the calibrator – in the case of a primary calibrator due to use of impure analyte and incorrect value assignment by the reference method. Errors may also arise due to instability of the

Figure 11 Diagram to indicate the concentration ranges over which the various quantitative immunoassay technologies can be used; it provides only a very rough guide. [a]Heterogeneous enzyme immunoassay includes amplified systems. [b]Heterogeneous fluorescence immunoassay includes time-resolved fluorescence systems.

analyte, particularly in the case of a macromolecule in a dilute solution, or differences in the effect of the matrix between calibrator and sample material.

In the case of large molecules there is also the possibility of considerable antigen heterogeneity. Thus many hormones may be present as prohormones and fragments in addition to the hormone molecule itself; examples include the existence of the prohormone of adrenocorticotropic hormone (ACTH), fragments of parathyroid hormone, and macromolecular forms of prolactin and gastrin.[109] In other cases the antigen of interest may exist in both free and complexed forms, as in the case of prostate-specific antigen (PSA),[110] and oxidized and reduced, phosphorylated, and dephosphorylated forms, as in the case of troponin I.[109,111] Genetic variants will also exist in many instances and this may influence attempts to quantitate all molecular forms of the antigen. Glycation may also influence the accuracy of an immunoassay, sometimes producing subtle differences in specificity.[112]

Quality assurance (QA) is designed to ensure that the correct result is produced on the correct specimen at the correct time; the major concern in terms of the analytical phase focuses on producing the correct result and embraces both internal quality control and external quality assessment. In setting up protocols to monitor or control performance, the closer the analyte species and matrix parallel those of the sample the more reliable is the scheme; particular attention in the production of QA materials must be paid to the effects of lyophilization or stabilization techniques on the analyte of interest, together with the effects of freezing and thawing.

External quality assessment schemes allow comparisons of performances to be made between methods with respect to both accuracy and precision. Such schemes have been valuable in improving the performance of quantitative immunoassays, particularly for larger biological molecules.[113,114]

8.2 Automation

A quantitative assay will benefit from automation of the various steps, especially when there are multiple reagents, additional mixing, and separation and washing steps involved. The homogeneous assay format has been configured for routine automated analytical instruments to achieve highly reproducible performance.

Whilst the heterogeneous format provided a greater challenge, in particular the separation and washing steps, full automation has now been achieved in many examples that have been commercialized.[115] In terms of the research laboratory, automation may be limited to the use of a multihead pipet, a microtiter plate, and an associated washing device. This has proved successful although care must be taken with (1) reproducible adsorption of reagent species to each reaction well and (2) avoidance of temperature gradients across the plate. An alternative semiautomated approach suitable for the research laboratory is to use a pipeting stage with a magnetizable solid phase, it being the most readily maintained in a homogeneous mixture for pipeting purposes.

8.3 Hapten Assays

A wide range of immunoassays for haptens have been described, including therapeutic drugs, drugs of abuse, and steroid hormones. Many of the assays for drugs have employed homogeneous techniques, their concentration ranges lying within the range 10^{-6}–10^{-9} M. The lower limit of detection is best exemplified by the assay for digoxin which approaches the limits of the majority of homogeneous formats.[116] Furthermore, the homogeneous formats, in many instances the subject of patented technology, have not been described for the more esoteric assays with limited commercial requirements.

Heterogeneous immunoassay formats have been described for a range of analytes but are generally confined in common usage to analytes of a lower concentration range. The heterogeneous approach is more readily set up where a limited usage is envisaged and consequently most of the more esoteric assays have only been described in this format.

Some examples of the performance that can be expected for haptens are illustrated in Table 3. A number of disposable devices for the detection of haptens have also been developed; some examples are given in Table 4.

Table 3 Some examples of immunoassays for haptens

Analyte	Technique	Between-batch precision (CV, %)	Analytical range	Ref.
Theophylline	EMIT®	4.2–5.2	0–40 mg L^{-1}	117
Cortisol	FETI[a]	3.9–6.8	400–1400 nmol L^{-1}	118
Digoxin	Immunometric (enzyme label)	1.0–8.0	0–5 μg L^{-1}	119
Digoxin	CEDIA®	3.5–12.0	0–4 μg L^{-1}	120
Cyclosporin	Heterogeneous chemiluminescence	2.0–11.4	25–1600 μg L^{-1}	121

[a] FETI, fluorescence excitation transfer immunoassay.

Table 4 Some examples of disposable devices for detection of haptens

Analyte	Technology	Sample	Ref.
Drugs of abuse	Lateral flow	Urine	102
Estrone 3-glucuronide	Lateral flow	Urine	122

8.4 Macromolecule Assays

The main homogeneous format applied to the quantitation of large molecules is that of the light scattering technique, it being the most popular approach for the quantitation of individual proteins. Sensitivity of detection has been enhanced by the use of latex particle-labeled antibodies. The method has been demonstrated over a sample concentration range of $10\,\mu g\,L^{-1}$–$50\,g\,L^{-1}$, which equates to a molar range of approximately 0.56 nm–0.75 mM.[61]

The immunometric format has been described, using a wide range of labels referred to earlier and capable of detection down to 10^{-19} M. Selection of antibodies is critical to the accuracy of the assays, as has already been mentioned. Some examples of the assays developed for macromolecules are described in Table 5. Disposable devices for a range of macromolecules have been developed; some examples are given in Table 6.

8.5 Limitations and Interferences

Reference has already been made to some of the limitations of the techniques described, particularly in the case of the quantitative assays, with reference to the design of immunogen, selection of antibody reagent, and the choice of solid phase.

8.5.1 Reagents

Dilute solutions of proteins are invariably unstable and therefore storage of reagents is critical; freezing and thawing may also harm immunoreagents. Similarly, calibrators may not be present in an identical matrix to the unknown samples and thus stability characteristics may differ. Batches of solid phase may differ and blocking conditions to minimize nonspecific binding may require reoptimization. Finally, different batches of reagents may change in relation to their potency, and careful optimization is important, as is validation with respect to accuracy and calibration range, prior to routine use.

8.5.2 Sample

In addition to the question of analyte stability, the most important concern with any sample is the potential presence of interferents. This is particularly important in the case of homogeneous assays; examples include endogenous enzymes that mimic the enzyme label

Table 5 Some examples of immunoassays for large molecules

Analyte	Technique	Between-batch precision (%)	Analytical range	Ref.
Thyrotropin	Enzyme-amplified microtiter plate, manual	5.1–9.8	0.6–$15.0\,mIU\,L^{-1}$	123
Creatine kinase MB	Enzyme label, bead, manual	6.3–11.0	0–$120\,\mu g\,L^{-1}$	124
Albumin (urine)	Latex particle immunoinhibition	1.4–8.8	0–$250\,mg\,L^{-1}$	79
Bone alkaline phosphatase	Immunocapture microtiter plate	4.3–6.7	0–$210\,IU\,L^{-1}$ at 37 °C	112
Bone alkaline phosphatase	Immunometric ^{125}I label, bead	7.1–8.3	0–$120\,\mu g\,L^{-1}$	112
Cystatin C	Latex particle nephelometry	3.2–4.4	0.23–$7.25\,mg\,L^{-1}$	125
Thyrotropin	Enzyme, chemiluminescent, manual	2.5–4.2	0.005–$60\,mIU\,L^{-1}$	44
Troponin T	Peroxidase, absorbance, tube, automated	2.0–5.8	0–$20\,\mu g\,L^{-1}$	126

Table 6 Some examples of disposable devices for the detection and/or quantitation of large molecules

Analyte	Technology	Sample	Lowest detectable amount	Ref.
Troponin I	Lateral flow, gold label	Whole blood	$0.1\,\mu g\,L^{-1}$	127
Troponin T	Lateral flow, gold label	Whole blood	$0.2\,\mu g\,L^{-1}$	128
Luteinizing hormone	Lateral flow, latex particle blue	Urine	–	122
Albumin	Direct agglutination, cassette	Urine	$1\,mg\,L^{-1}$	129
HbA_{1C}	Latex immunoinhibition, cassette	Whole blood	–	98
C-reactive protein	Lateral flow, gold label	Whole blood	$12\,mg\,L^{-1}$	130
Chorionic gonadotrophin	Lateral flow, latex particles, blue	Urine	$1.9\,\mu g\,L^{-1}$	131
Chorionic gonadotrophin	Flow through	Serum	$5\,\mu g\,L^{-1}$	100

reaction (e.g. an NAD → NADH conversion in the presence of pyruvate and lactate dehydrogenase) and the interference in fluorescence assays due to endogenous light scattering, endogenous fluorescence, or the presence of quenching agents. It should also be remembered that samples may sometimes contain exogenous compounds that may interfere (e.g. drugs). Fewer problems are likely in the case of the heterogeneous assay, although the problem of binding proteins, whether normally present or abnormal, may cause problems in any assays; the presence of antispecies antibodies, and heterophilic antibodies can cause particular problems, particularly in the case of heterogeneous immunoassays.[132]

9 CONCLUDING REMARKS

Readers will see from this article that immunochemistry is a huge field in terms of basic chemistry, biochemistry, analytical chemistry, and applied science. The discussion has attempted to illuminate readers' understanding of the basic aspects of the antigen–antibody reaction and in so doing illustrate how it can be exploited for the recognition and quantitation of biomolecules. Some examples have been given to indicate the ingenuity of research scientists in this field.

ABBREVIATIONS AND ACRONYMS

ABDP	*N*-(4-Aminobenzoyl)-*N*′-(pyridyldithiopropionyl)hydrazine
ACTH	Adrenocorticotropic Hormone
AMPPD	3-(2′-Spiroadamantane)-4-methoxy-4-(3″-phosphoryloxy)-phenyl-1,2-dioxetane
ATP	Adenosine Triphosphate
CD	Cluster of Differentiation
CDR	Complementarity-determining Region
CEDIA	Cloned Enzyme Donor Immunoassay
CZE	Capillary Zone Electrophoresis
DELFIA	Dissociation-enhanced Lanthanide Fluorescence Immunoassay
DPEM	*N*-[β-(4-Diazophenyl)ethyl]maleimide
ELISA	Enzyme-linked Immunosorbent Assay
EMIT	Enzyme-multiplied Immunoassay Technique
FAD	Flavin Adenine Dinucleotide
FETI	Fluorescence Excitation Transfer Immunoassay
GC	Gas Chromatography
HAT	Hypoxanthine, Aminopterin, and Thymidine
HPLC	High-performance Liquid Chromatography
HSAB	*N*-Hydroxysuccinimidyl 4-Azidobenzoate
LOCI	Luminescent Oxygen Channeling Assay
MBS	*m*-Maleimidobenzoyl *N*-Hydroxysuccinimide
NAD	Nicotinamide Adenine Dinucleotide
NADH	Reduced Nicotinamide Adenine Dinucleotide
NADP	Nicotinamide Adenine Dinucleotide Phosphate
PSA	Prostate-specific Antigen
QA	Quality Assurance
SELEX	Systematic Evolution of Ligands by Exponential Enrichment
TPA	Tripropylamine
TSH	Thyroid-stimulating Hormone

Infrared (IR) spectroscopy measures the absorption of IR radiation by chemical bonds in a material. Chemical structural fragments of molecules, known as functional groups, tend to absorb IR radiation in the same frequency range regardless of the structure of the rest of the molecule in which the functional group is located. This correlation between the structure of a molecule and the frequencies at which it absorbs IR radiation allows the structures of unknown molecules to be identified and structural or chemical changes of the molecule to be followed. Traditionally, IR spectroscopy has been one of the most important physical methods in the chemical laboratory as it plays an important role in the elucidation of structures and the identification of organic and inorganic compounds. The quantitative analysis of samples is straightforward and is not affected by the physical state of the sample. Gaseous, liquid, and homogeneous and inhomogeneous solid samples all can be conveniently studied.

Applications of IR spectroscopy in clinical chemistry have progressed rapidly in recent years. IR pathological analysis is becoming increasingly important in the detection of biochemical changes in body fluids and tissues. Information obtained from their IR spectra can be used to identify diseases. Advanced investigations are carried out using different data-analysis techniques such as multivariate analysis. Using a pattern-recognition approach, IR spectroscopic data provide a nonsubjective aid in the diagnosis of the disease state and the staging of the disease. Unlike most colorimetric or electrochemical/enzymatic clinical chemistry assays, IR spectroscopic analysis is applicable to a variety of body fluids and tissues: whole blood, plasma or serum, synovial fluid, saliva, urine, cells, and membranes. The methodology is fast and readily automated. Sample preparation is simple and no special reagents or other consumables such as electrodes are required, making IR spectroscopy a low-cost operation. The most attractive advantage of the method is the potential for a rapid multicomponent analysis to be carried out from a single spectrum.

1 INTRODUCTION

IR spectroscopy measures the absorption of IR radiation by chemical bonds in a material. Chemical structural fragments of molecules, known as functional groups, tend to absorb IR radiation in the same frequency range regardless of the structure of the rest of the molecule in which the functional group is located. This correlation between the structure of a molecule and the frequencies at which it absorbs IR radiation allows the structures of unknown molecules to be identified and structural or chemical changes of the molecule to be followed.

The energy of a light wave is directly proportional to its frequency. The frequency is in turn related to the velocity of light by a parameter called the wavenumber, which is defined as the reciprocal of the wavelength of the light wave (Equations 1 and 2):

$$\text{energy} = hcW \tag{1}$$

$$\text{frequency} = cW \tag{2}$$

where h = Planck's constant (6.63×10^{-34} J s) c = velocity of light (3×10^{8} m s^{-1}), and W = wavenumber (cm^{-1}). Wavenumbers are the units typically used in IR spectroscopy to denote different energies.

Qualitatively, the chemical bonds present are identified by the frequencies at which they absorb IR radiation and

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

vibrate. For example, the C=O stretching vibrational mode of a carbonyl group occurs at $\sim 1700\,cm^{-1}$ in carboxylic acids, ketones, and aldehydes. Quantitative IR spectroscopic analysis determines the concentrations of molecules in a sample. The molecule of interest is called the analyte. For absorption spectroscopy, the intensity of a spectral band can be represented by the height or area of a peak in an absorbance spectrum. The law relating band intensity to concentration of analyte in the IR beam is the well-known Bouguer–Beer–Lambert law, which we shall abbreviate to Beer's law. For a single analyte at low concentration, in a nonabsorbing solvent, Beer's law gives the absorbance at any wavenumber according to Equation (3):

$$A = \log\left(\frac{1}{T}\right. \quad = alc \tag{3}$$

where A = absorbance, T = transmittance at the wavenumber, a = absorptivity at the wavenumber, l = pathlength, and c = concentration of the analyte. Transmittance is defined according to Equation (4):

$$T = \frac{I}{I_0} \tag{4}$$

where I = light intensity with a sample in the beam and I_0 = light intensity with no sample in the beam.

For a mixture of N analytes, the absorbance at a specific wavenumber is the sum of the absorbances of all analytes which absorb IR radiation at that wavenumber. Hence the quantitative analysis of samples is straightforward and can be reliable down to the picogram level for molecules with a high molar absorptivity. Furthermore, IR spectroscopic analysis is not affected by the physical state of the sample: gaseous, liquid, and homogeneous or inhomogeneous solid samples all can be conveniently studied.

The ''routine'' IR spectroscopy in use at the present is Fourier transform infrared (FTIR) spectroscopy. There are many reviews of FTIR spectroscopy which describe the theory, hardware, techniques, and applications.[1–7] Briefly, the development of FTIR spectroscopy began with the invention of the Michelson interferometer. The purpose of an interferometer is to take a beam of light, split it into two beams, and make one of the light beams travel a different distance than the other. The difference in distance traveled by these two light beams is called the optical path difference. A diagram of a Michelson interferometer is shown in Figure 1. In the Michelson interferometer, an optical path difference is introduced between the two light beams by translating the moving mirror away from the beamsplitter. The light that reflects off the moving mirror will travel further than the light that reflects off the fixed mirror. For monochromatic light, different optical path differences create constructive and destructive interference and the light-beam intensity varies between very bright and very weak. A plot of light intensity versus optical path difference is called an interferogram. A broad-band IR source gives off light at a continuum of wavelengths and each frequency component gives rise to a different wave interferogram. The total interferogram measured by the detector is the summation of all the interferograms from all the different IR frequencies. A simplistic way to think about the process is that the interferometer ''encodes'' the intensity and wavelength information so that all the data can be measured at once, and the Fourier transform decodes the information to obtain the absorbance versus wavenumber spectrum.

Figure 1 Schematic diagram of an FTIR spectrometer.

The ultimate performance of any spectrometer is determined by measuring its signal-to-noise ratio (S/N). The S/N is calculated by measuring the peak height of a feature in an IR spectrum (such as a sample absorbance peak) and ratioing it to the level of noise at some baseline point nearby in the spectrum. Noise is usually observed as random fluctuations in the spectrum

above and below the baseline. There are two reasons why FTIR spectrometers are capable of significantly higher S/Ns than the old dispersive instruments. The first is called the throughput advantage of FTIR spectroscopy. It is based on the fact that all the IR radiation passes through the sample and strikes the detector at once in an FTIR spectrometer. Hence, the detector sees the maximum amount of light at all points during a scan. The second S/N advantage of FTIR spectroscopy is called the multiplex advantage. It is based on the fact that in an FTIR spectrometer all wavenumbers of light are detected at once. The noise at a specific wavenumber is inversely proportional to the square root of the time spent observing that wavenumber. Because of the multiplex advantage, acquiring data for 10 min on an FTIR spectrometer means that all wavenumbers are observed for a full 10 min. The practical advantage of the multiplexing is that an FTIR spectrometer can acquire a spectrum much faster than a dispersive instrument. This allows multiple scans of the same sample to be added together. For a constant resolution, the S/N is proportional to the square root of the number of scans added together. Thus, a spectrum consisting of 100 added spectra would have an S/N 10 times better than a spectrum comprised of just one scan. Table 1 lists the S/N improvement for various number of scans compared with a single scan.

Despite the many advantages of FTIR spectroscopy, there are limitations on what is achievable with IR spectroscopy in general, and there is one specific limitation of the FTIR technique in particular. A general limitation of FTIR spectroscopy is that it cannot detect atoms or monoatomic ions since these species do not contain chemical bonds, do not posses vibrational motion, and thus do not absorb IR radiation. Homonuclear diatomic molecules do not give IR spectra owing to their symmetry. Another limitation of IR spectroscopy is its use in analyzing complex mixtures. These samples give rise to complex spectra which are difficult to interpret. Fortunately, special data-analysis techniques are now available to aid the interpretation of these complicated spectra. Some of these methods will be discuss in detail in section 3.

Table 1 Number of scans and S/N improvement

Number of scans	S/N improvement
1	–
4	2
16	4
64	8
100	10
400	20
1024	32

It is also difficult to analyze aqueous solutions using IR spectroscopy because water dissolves many IR-transparent materials and water is also a strong IR absorber. Special window and cell materials are available for aqueous solutions and special techniques are available to obtain spectra of aqueous solutions. These will be discussed in section 2.

A specific limitation of FTIR spectroscopy is that most FTIR spectrometers are single-beam instruments. The background spectrum which measures the contribution of the instrument and the environment to the spectrum is measured at a different time than the spectrum of the sample. The sample spectrum is then ratioed to the background spectrum to eliminate the contributions of the instrument and environment. If there are changes in the instrument or the environment between the times when the sample and background spectra are obtained, artifacts can appear in the sample spectrum. This can be overcome by using purging boxes.

There are many general reviews of FTIR spectroscopy which describe the hardware, techniques, and applications and some representative ones are cited here.[1–7]

2 SPECIALIZED INSTRUMENTATION FOR CLINICAL CHEMISTRY STUDIES

Obtaining the IR spectra of biological samples is a new and rapidly expanding field. One difficulty of this application is that biological samples are complex and usually in aqueous solutions. Complex mixtures give complex spectra that require special detection methods and special data-analysis techniques. On the other hand, IR spectroscopy has high sensitivity, is easy to perform, requires little or no sample preparation, is generally reproducible, and is rapid and inexpensive, being able to identify many components all at once.

IR spectroscopy offers a number of advantages for the analysis of body fluids. Unlike most colorimetric or electrochemical/enzymatic clinical-chemistry assays, IR spectroscopic analysis can be applied to a variety of biofluids such as whole blood, plasma, serum, synovial fluid, saliva, and urine. As an in vitro diagnostic and pathological analytical technique, the methodology is fast and readily automated, making it suitable for use as a routine technique in the clinical-chemistry laboratory. As an in vivo monitoring technique, it is noninvasive and has great promise as an accurate, rapid tool to monitor progress and response to therapy in patients. IR spectrometers can be made compact, rugged, relatively inexpensive, and user independent, making the technology capable of point-of-care operation in the emergency room, critical care unit, and general practitioner's office, and potentially

even as a home monitoring device. Since no reagents or other consumables are required, IR spectroscopy has a low operational cost. The most attractive advantage of the method is the potential for a rapid multicomponent analysis to be carried out from a single measurement.

IR spectroscopy for biological samples is usually performed in two frequency ranges: mid-IR from 4000 to 500 cm^{-1} and near-IR from 12 800 to 4000 cm^{-1}. The near-IR range is particularly useful for biological samples because water does not absorb in this range. IR bands in the near-IR region are combination and overtone vibrations arising from the C–H, O–H and N–H moieties of molecules whereas the bands which dominate the mid-IR region are fundamental molecular vibrations of all functional groups. Thus, the near-IR and the mid-IR regions carry different information contents. The near-IR assays of substrates such as total protein, total cholesterol, and triglycerides compare well in performance with those which use the mid-IR range.

2.1 Transmission Spectroscopy

In this technique, the sample is placed in the light beam of the spectrometer and the intensity of the incident beam is compared with the intensity transmitted by the sample (Figure 2). The concentration of the absorbing sample is calculated directly using Beer's law. The transmission method is widely used, primarily because it produces spectra with high S/N and requires only simple accessories. Liquid samples have generally been measured in fixed-path-length transmission cells. The transmission path length is usually dictated by the absorption characteristics of the liquid sample matrix. Owing to the high water absorptivities in the mid-IR region, aqueous samples are limited to path lengths of less than 0.03 mm. Another requirement for quantitative analysis in the mid-IR range is the use of an IR-transparent window material that is compatible with the water matrix. Table 2 lists commonly used window materials for transmission spectroscopy of aqueous solutions.

Figure 2 Transmission IR spectroscopy.

2.1.1 Transmission Difference Spectroscopy

Transmission difference spectroscopy uses the spectral subtraction technique. A ''reference'' spectrum is subtracted from a ''sample'' spectrum to obtain the ''difference'' spectrum. The difference spectrum indicates the changes in concentrations of chemical species present in the original reference spectrum or the appearance of new species in the sample spectrum. Transmission difference spectroscopy is ideal for tracking reactions or detecting small changes in the original species as a function of time,

Table 2 Optical materials for IR spectroscopy of aqueous solutions

Window material	Useful range (cm^{-1})	Refractive index at 2000 cm^{-1}	Properties
LiF	83 000–1400	1.33	Slightly soluble in water, suitable for near-IR
CaF_2	77 000–900	1.40	Insoluble in water, resists most acids and alkalis
BaF_2	66 666–800	1.45	Insoluble in water, soluble in acids and NH_4Cl, good resistance to F and F^-
AMTIR	11 000–725	2.5	Hard, brittle, insoluble in water, attacked by alkalis, good for ATR
AgBr	22 000–300	2.3	Insoluble in water, soluble in acids and NH_4Cl, corrosive to metals and alloys
KRS-5	17 000–250	2.38	Slightly soluble in water, soluble in bases, not soluble in acids, good transmission, ideal for ATR, highly toxic
Fused silica	40 000–3000	1.46	Unaffected by most solvents, good for near-IR
ZnS	50 000–770	2.25	Insoluble in water, normal acids and bases, and virtually all organic solvents, reacts with strong oxidizing agents
ZnSe	20 000–500	2.43	Insoluble in water, high resistance to chemical attack, ideal for ATR
Ge	5000–550	4.01	Insoluble in water, soluble in hot sulfuric acid and aqua regia, suitable for ATR
Si	8333–33	3.42	Very hard and inert crystal, suitable for ATR in selective spectral range

ATR, attenuated total reflection.

chemical environment, or reaction. Spectral subtraction of spectra of biological molecules will be discussed in more detail in section 3.

2.1.2 Near-infrared Spectroscopy

Measurement of aqueous fluids in the near-IR region is almost exclusively carried out in the transmission mode. Unlike in the mid-IR region, near-IR transmission cells can be made from conventional glass or quartz window material. The cell path length in the short-wavelength near-IR range (6000–12 500 cm^{-1}) can be about a factor of 10 greater for physiological fluids than in the longer wavelength range. This is because of the reduced water absorptivities observed in this range. The longer path-length requirement is more convenient, but it also dictates a larger sample volume which may not be readily available for certain biofluids.

2.2 Reflective Techniques: Attenuated Total Internal Reflection

For ATR spectroscopy, the sample is brought near a crystal of IR-transparent material of high refractive index where the light is totally internally reflected and where the sample interacts with the evanescent wave (Figure 3). The effective path length for this interaction (the depth of penetration of the IR beam into the sample) is typically a fraction of a wavelength, and depends on many parameters, making ATR a very powerful technique. Recently, the ATR technique has experienced a resurgence in popularity in the analysis of biological samples, primarily owing to its suitability for studies of aqueous solutions. Internal reflection is also nondestructive. For example, to record the spectrum of the skin on one's finger via transmission spectroscopy, one must cut a thin slice of the skin, whereas via ATR spectroscopy one need only place the finger in contact with the optical element.

ATR is the IR spectroscopic method of choice for aqueous solutions. ATR crystals are impervious to water and the short path lengths mean that water will not be totally absorbing. This allows water to be subtracted from sample spectra so that the spectra of solutes in aqueous solutions can be obtained. A disadvantage of liquid ATR spectroscopy is that it is not very sensitive because the path lengths are small. Special efforts have to be made to detect solutes at concentrations less that 0.1%. For quantitative work, it is important to have a way to position the crystal in the sampling accessory reproducibly such that the depth of penetration is controlled. The same ATR crystal must be used for standards and samples when performing quantitative analyses. The crystal must be kept clean and scratch free. Scratches on an ATR crystal affect sample–crystal contact and thus influence the depth of penetration. The most commonly used ATR crystal materials are listed in Table 2.

Figure 3 ATR spectroscopy.

2.3 Infrared Microspectroscopy

IR microspectroscopy is the coupling of optical microscopy and IR spectroscopy. IR microspectroscopy is attractive because it combines IR spectroscopy's ability to identify subtle differences in the chemical components and optical microscopy's capability to resolve spatially the location of sample features. It allows the visual and IR examination of different parts of the sample on the microscopic scale. This technique is particularly attractive because it is highly sensitive. The IR microscope can be used in four ways: visual transmission, visual reflection, IR transmission, and IR reflection. Detailed descriptions of microscope designs can be found in the literature.[8–12] In IR microscopy, it is imperative that the sample and background spectra be run using the same settings. This is as important as using the same number of scans and the same resolution for these spectra. The sample spectrum is usually taken before the background spectrum and the two spectra are ratioed at a later time to obtain the absorbance or transmittance spectrum. IR spectra of microscopic samples can also be obtained in reflectance. The sample is typically mounted on a gold mirror and the IR beam is reflected off the sample. The background spectrum is obtained by reflecting the IR beam off a clean portion of the gold mirror.

IR microspectroscopy has great potential as a biochemical and biomedical probe. In contrast to conventional histological techniques, IR spectral images are derived from the intrinsic vibrational properties of the biological components. The IR spectra reflect changes in biochemical and biophysical properties resulting from disease or toxic injuries. Using IR microspectroscopy, these intrinsic changes across a sample can be visualized.

Kidney stones, arteries, and individual cells have been studied using this technique. One of the most exciting developments in the field is the discovery that healthy and cancerous cells have different IR spectral features.[10–14]

Chemically induced DNA damage that prompt the progression of cancers to the metastatic state can also be detected.[10]

2.3.1 Mapping

To define the area of the sample to be analyzed, physical apertures are placed in the beam path such that radiation is sampled only from a well-specified region of the sample. To acquire spatially resolved spectral images using this technique, a sampling area is first defined by the apertures. Spectral data are then obtained from this region, the sample is moved so that the apertures are focused on an adjacent portion of the sample, and spectral data are again obtained. The whole process is repeated until the desired sampling region is mapped. A high S/N spectrum with 4 cm^{-1} resolution in the 700–4000 cm^{-1} range can be obtained in ~30 s in a typical case. The smallest regions that can be probed are on the order of 15 μm. The major drawbacks of using mapping for the collection of spatially resolved images are the long collection times and the limited spatial resolution.

2.3.2 Imaging

FTIR spectral imaging can be accomplished by a new instrument that incorporates a step-scan Fourier transform interferometer, a microscope, and a focal plane array. This instrument simultaneously obtains high-resolution IR spectra for each pixel of a two-dimensional imaging array. This new technique has been applied to the identification of leaking silicone from breast implants, metastatic cells and tissues, and neurotoxicity.[1,12] It shows great promise for diagnosis of pathologies resulting from disease and toxic insult.

3 DATA-ANALYSIS TECHNIQUES

The raw data obtained from an FTIR spectrometer are often put through spectral manipulations. The main goal of such spectral manipulations is to extract more information, which can supply possible hints for further interpretations. Understanding and working with the IR data is crucial because the raw measurements often appear simple yet contain much qualitative and quantitative information. As researchers struggle to glean insights into the studies of bioanalytical and clinical samples with FTIR spectroscopy, various approaches are developed and utilized. Currently, there are many types of software which will allow quick access to these methods. The following are a few generally well-accepted methods especially applicable to clinical-chemistry research. In a chapter on the proper use of spectral manipulations, Smith stresses the importance of protecting the integrity of the data.[1] He recommends two very practical rules: (i) always retain a copy of the unaltered spectrum and (ii) always note what kind of spectral manipulations have been performed. One needs to have a clear understanding of both the principles and the logical path involved in the techniques to be able to interpret the resulting data fully. The section on each method will contain brief discussions of the principles, applicability, advantages, and limitations.

3.1 Spectral Subtraction

As early as the late 1960s, researchers studying proteins, DNA and peptides attempted to address the overwhelming, broad water absorption band in the mid-1600 cm^{-1} wavenumber range. The importance of the amide I, amide II, and amide III bands in studies of the biochemical and clinical samples is well established. Unfortunately, amide I bands (due to the carbonyl absorption of amides), amide II bands (due to N–H bending) and amide III bands (due to C–N stretching) associated with these samples invariably cluster in the same general range as that of the water band mentioned above. It was necessary for researchers to find a way to get past the opaque, large absorption of the water in order to ''see'' the information contained in the spectra of the sample in aqueous solution. Spectral subtraction is a method well suited for this purpose.

The principle behind spectral subtraction is easy to understand. A spectrum of a mixture such as a protein being studied in solution is called a ''sample'' spectrum. On the other hand, a ''reference'' spectrum is one component of the mixture such as water for the above example. A set of subtractions can be performed, point-by-point, to subtract away the absorbance values of the reference from the sample spectra to obtain the difference. When performed following certain stipulations, the results can show peaks attributable to the nonreference material, which were previously hidden.[1]

A closer examination of the above principle reveals that the validity of Beer's law must hold for both spectra in question. Specifically, the absorbance measured by the spectra must be linearly proportional to concentration. Usually, the concentrations of the sample and the reference will not be exactly the same. If the linearity relationship holds for the two spectra, however, the reference spectrum can be multiplied by a factor to resolve this problem.

When computer software is used, the following procedural steps may be helpful:

1. Place the absorbance spectra of the sample and the reference on the same screen and compare the two. The peaks that are common to both belong

to the reference material. Identify these common features. If the reference spectrum is one which is well established (e.g. water, saline, methanol), one of these common peaks may be easily identified as the characteristic peak to be normalized.

2. Pick a common peak and use the ''interactive'' feature of the software to experiment with subtraction factors. Keep in mind that the factor chosen will fit into the subtraction Equation (5):

$$(\text{sample}) - (\text{factor})\,(\text{reference}) = \text{results} \qquad (5)$$

The goal is to subtract out this common peak and produce a flat section. When the factor is too small, the reference peak will still remain. On the other hand, a large factor will produce negative peaks pointing downwards. It is usually possible to expand the wavelength range near the peak in question to achieve successively better results. A subtraction factor slightly above or below 1000 gives the best results. This is an indication that the concentrations of the two spectra are similar. Sometimes, an internal reference may be used. An internal reference is a molecule which absorbs at a wavelength different from the reference and the sample. The absorbance of the internal reference is then used to adjust the subtraction factor.

3. Go back and examine visually the three spectra: sample, reference, and results. Evaluate for two types of possible artifacts. When linear proportionality does not hold for a certain section of the wavelength, jagged remnants of the subtraction may show as artifacts. The second type of artifacts appear as relatively sharp peaks above and below the baseline resembling a derivative curve. These artifacts are often caused by shifts in the reference peaks due to the chemical interactions occurring in the mixture. When these artifacts are apparent but are located in the nonessential wavenumber range, one may be able to disregard these artifacts and focus on the crucial section of the spectrum. In addition, it will be wise to check to see if in fact additional information can be gained from the overall subtraction results.

Once the approach to the water subtraction is perfected, application for the general method of spectral subtraction is greatly expanded. Using the label, ''difference spectra'', one may subtract any known component spectra from the mixture. In addition, it is reasonable then to obtain the spectra of the same sample under different conditions and perform subtraction. In fact, Griffiths and de Haseth call attention to the fact that ''Much of the work described since 1980 has made use of spectral subtraction techniques to focus on reactions or interactions taking place on specific sites of large molecules''.[7] In their studies of the metal–DNA interaction, Tajmir-Riahi et al. utilized the difference spectra algorithm [(DNA solution + metal cation solution) − (DNA solution)].[15,16] They mentioned the use of certain DNA bands as an internal reference. They reasoned that the band at 893 cm^{-1} was useful because its absorbance is due to deoxyribose–phosphate vibrations and exhibited no change upon complexation of DNA with cation. In other words, this band will cancel out completely when subtraction is performed.

Criteria for water subtraction can be spelled out as part of the experimental methods. For an example, Olinger et al. specified the following: (i) a straight baseline from 2000 to 1725 cm^{-1} and (ii) no lobes with a negative absorbance.[17]

The main data-analysis method used by Rothschild et al., in their studies of the light-activated membrane protein bacteriorhodopsin, was also difference spectrometry.[18] By performing subtraction, they were successful in pinpointing the absorption changes due to the alterations in the protein. Bagley et al.[19] also studied rhodopsin but took the FTIR subtraction method a step further. They were successful in setting up an innovative experimental design whereby three different products of ''photosequence'', rhodopsin, bathorhodopsin and isorhodopsin, were compared. Owing to the light absorption, rhodopsin is known to go through a sequence of changes, which triggers electrical conversion of the photoreceptor cell membrane. This conversion of electrical properties, in turn, results in the neural signal. By pairing the three products (bathorhodopsin–rhodopsin, bathorhodopsin–isorhodopsin, and isorhodopsin–rhodopsin) and calculating the difference spectra for each pair, they were able to obtain information regarding ''the protein–chromophore linkage, isomeric state, and opsin conformation''.[19] Griffiths and de Haseth cited a biocompatibility study of synthetic polymers as one of the example of applications of FTIR spectroscopy to biomedicine.[7] To study the changes in blood proteins as they are adsorbed on a polymer surface, they utilized two types of subtractions. For each spectrum, water subtraction was conducted to obtain the spectrum of the adsorbed protein. As these researchers were interested in the complex changes that occur with time, several scans representing certain time intervals were paired and subtracted from each other. Hence, the study was able to focus on the detailed differences occurring during the timescale of the experiment.[19]

Advantages and some practical considerations regarding the use of ATR in studies of whole blood and plasma were carefully outlined by Wang et al.[5] They caution against achieving a single water subtraction factor

when various thickness and concentrations of biofluids are studied. Water, blood, and plasma can have different refractive indices and penetration depths of the evanescent waves. The resulting spectra may show high variability in intensities. Therefore, it is especially important to be mindful of the conditions affecting the subtrahend in the clinical analysis of biofluids.

In summary, spectrum subtraction is a relatively simple, yet useful data-analysis technique, which has been applied in several resourceful ways by various researchers. Smith reminds any user of this method that "very few subtractions are perfect".[1] Most of all, one needs to keep in mind the linearity stipulation regarding the concentration of the sample and the reference (Beer's law).

3.2 Spectral Derivatives

Many of the articles and reviews on spectral derivatives mention the original study of the second-derivative spectra of proteins in ^2H_2O by Susi and Byler.[20] In 1983, they explained the use of the second-derivative Fourier transform spectra in relation to the resolution of inherently broad, overlapping protein bands. They presented a comparison of the original spectrum and its second derivative (in graphical form) in order to pinpoint the additional information gained by the process. They stated that, "the second derivative of the original spectra offers a direct way to identify the peak frequencies of characteristic components and thus permits much more detailed qualitative and, eventually, quantitative studies".[20]

Smith points out that "an IR spectrum is a mathematical function".[1] Therefore, one can calculate and determine the slope of such function by taking the *derivative*. Currently, most computer software will furnish several methods, such as "point difference" and "Savitsky–Golay", which will calculate several orders (i.e. first through ninth) of derivatives. In most cases, the analyst need only enter the desired number for the order (first = 1, second = 2, etc.) of the derivative. There are no complicated parameters to be chosen or considered for this process!

Actually, the main purpose of obtaining the derivatives is *not* to obtain the value of the "slope", but to use the information contained in the resulting derivative spectrum. As implied in the previous paragraph, the second derivative is most useful because it contains three features corresponding to each peak in the original spectra. In particular, "the bottom of the downward-pointing feature"[1] pinpoints the exact wavenumber of the maximum absorbance of the peak. These wavenumbers, then, can be used in turn to estimate the number of overlapping bands in the composite and to locate their possible peak positions. A further explanation of the use of the derivatives is given in the section 3.3.

When calculating and utilizing the second derivative, care must be taken to keep "the increase in noise and/or the appearance of side lobes at a minimum".[21] The absorbance interferogram will be multiplied by a parabolic weighting function of the form $F(x) = ax^n$ $(n = 2)$ in the process of the second-derivative calculation. The effect of this multiplication, unfortunately, is to amplify the noise at high retardations.[7] In the regions of high retardation (regions further out from the base of the peak), generally, the signal level is already lower and the noise tends to be constant and predominant even before the multiplication. At the same time, since it can be proven that "best resolution = maximum retardation",[7] it will be helpful to experiment to find the appropriate level of "resolution" *prior* to taking the derivatives. Often, a resolution of $2\,cm^{-1}$ is used for the original spectra. Perhaps this consideration should be taken into account when the original spectrum is actually measured, long before the analysis stage. Users should keep in mind the following rule of thumb: "each time the order of the derivative is increased by two, the S/N of the spectrum will degrade by approximately an order of magnitude".[7]

In summary, the computational procedure of taking the spectral derivatives is commonly utilized to estimate the number of smaller bands contained in a large composite band and to locate specific peak positions. Computational execution for the process is simple using, for example, the "point difference" method in suitable software. Since the number and the peak positions are needed in the data-analysis method referred to as "deconvolution", the application of the spectral-derivative method will be discussed in the next section.

3.3 Deconvolution

Deconvolution can be one of the most useful and powerful methods of interpreting spectra. At the same time, its use can easily be challenged. Therefore, the literature abounds in reviews of the method, evaluations of its merits, applications, etc.

Biochemical analysis of protein secondary structure continues to be a popular topic of investigation, originating in the late 1970s to early 1980s. As mentioned previously, the amide I band is often studied in relation to the changes in the protein structure. It is generally known that the amide I band consists of a number of overlapping component bands. Many researchers have attempted to establish the correspondence between the protein structural changes and the changes in the band components. This approach led to various attempts to resolve the large composite band into separate narrower bands for the purpose of identification.

In 1981, Kauppinen et al. developed a computational method that they entitled, "a digital self-deconvolution method".[22] It is known today as Fourier self-deconvolution (FSD) and is widely used as the most effective procedure for narrowing IR bands.[23] Again, some fundamental understanding of the procedure will be helpful when using the computer software.

An absorbance band can be expressed mathematically according to Equation (6):

$$A(\nu) = \frac{A_0\gamma^2}{\gamma^2 + (\nu - \nu_0)^2} \quad (6)$$

where A_0 = maximum absorbance, γ = half-width at half-height (HWHH) and ν_0 = wavenumber for maximum absorbance.[23] When this band is Fourier transformed, the resulting interferogram is expressed by Equation (7):

$$I(x) = F\{A(\nu)\} = 0.5A_0\gamma\cos(2\pi\nu_0 x)\exp(-2\pi\gamma x) \quad (7)$$

where x = a spatial frequency with units of centimeters. In this equation, the γ value determines the rate of the exponential decay. Therefore, the greater the width of the absorbance band, the quicker the transform will decay. If this process is taken in reverse, one could decrease the decay of the exponential term and thereby reduce the bandwidths of the spectrum. To achieve the decrease in the exponential decay, $I(x)$ needs to be multiplied by an exponentially increasing function. When the reverse Fourier transform is performed on the product, $I'(x)$ [i.e. $F^{-1}\{I'(x)\} = A'(\nu)$], a narrower absorbance band is obtained. The above process does, however, increase the noise in the same manner, requiring a smoothing function.

In a paper on the general theory of FSD, Kauppinen et al. listed three instrumental factors which limit the degree of resolution enhancement: in addition to the S/N of the spectrum, they include the dynamic range of the digitization and computational processes and the instrumental resolution used when the spectrum is recorded.[22] They continued to state that all three factors result in the truncation of the interferogram. This truncation, in turn, results in the introduction of artifacts called side-lobes into the spectrum. The multiplication of the interferogram by an apodization function, prior to the performance of the reverse Fourier transform will eliminate these side-lobes. Instruction regarding apodization will be given in the next section.

The following suggestions may be useful with most computer software on deconvolution:

1. Identify a band (or a group of bands) which most likely is composed of several smaller bands. These bands are often broad, asymmetric, and may contain a shoulder or two, giving suggestions of hidden bands. (Follow the software directions to define this region graphically.) The narrowest bandwidth of the group, measured at the half-height of the peak, must be broader than the instrumental resolution used for the original spectrum.
2. Smith states that "the most important user adjustable parameter in deconvolution is the amount of resolution enhancement".[1] This parameter, called the "resolution enhancement factor", is often denoted by γ or K. It is the ratio of the widths measured before and after deconvolution. In other words, K or $\gamma_{(\text{factor})} = \gamma_{(\text{before})}/\gamma_{(\text{after})}$, where γ = full width at half-height (FWHH). Several guidelines are outlined below which can be utilized to choose the appropriate value of the resolution enhancement factor.
   (a) Check the S/N of the spectra and use Table 3 to estimate the maximum.
   (b) Take the second derivative of the bands in the region to determine how many real bands can be expected and where they may be located (see section 3.2).
   (c) Experiment with the factor value until the resulting spectra shows the approximate number of expected bands in the defined wavenumber region. Overdeconvolution may show hundreds of new features with the possible appearance of high, regular, periodic noise features and large negative side-lobes (see the explanation regarding apodization for the side-lobes). Underdeconvolution will result in the bands retaining the shapes similar to the original spectrum. Bands may be only partially separated and/or not separated as expected from the derivative spectrum. In addition, the value of the spectral resolution may be lower than expected. According to Surewicz and Mantsch, "the condition that gives the maximum band narrowing while keeping the increase in noise and/or the appearance of the side-lobes at a minimum"[23] is the key. Apply the parameter for the resolution enhancement.
   (d) To eliminate the side-lobes, there are usually choices of apodization functions such as boxcar, triangular, and Bessel by which the interferogram can be multiplied. Again, experiment to

Table 3 Maximum resolution enhancement vs S/N

S/N	Maximum resolution enhancement factor
100 : 1	2
1000 : 1	3
10 000 : 1	4

achieve a good balance between the width of the bands and the amount of reduction of the side-lobes. Determine which function and what percentage of smoothing is desirable. Apply these parameters and let the software do the work!

Applications of deconvolution methodology provide the possibility of detailed protein secondary structural analysis.[23] The spectra resolved by FSD can be helpful in studying subtle spectral changes brought about because of an external parameter.[22] Once the correlation between resolved components in amide band areas and specific polypeptide structures have been established, researchers can design novel approaches to observe structural changes. Using various experimental designs, parameters such as temperature, pressure, concentration, pH, and solvent can be varied and the resulting detailed structural changes can be observed. Although applicable to all types of protein, Surewicz and Mantsch pointed out that the method is especially helpful in studies of membrane proteins in the hydrophobic environment of a lipid bilayer.[23] The IR study of this particular species of protein tends not to be hampered by the problems encountered in the X-ray diffraction or circular dichroism (CD) spectra (e.g. unavailability of quality crystals, distortions of CD spectra by large membrane fragments). A review by Surewicz and Mantsch includes a large section regarding the applications of resolution enhancement for studies of protein secondary structure.[23] They list studies of Ca^{2+} transport ATPase from sarcoplasmic reticulum, bacteriorhodopsin, myelin basic protein, β-lactoglobulin, methionine aporepressor from *Escherichia coli* and two peptide hormones. It is remarkable to see the variety represented in the experimental designs.

Investigations of protein structural changes using FSD frequently make comparisons of percentages of areas under the component bands with percentages of the conformational structures (α-helix and β-turns, etc.) referenced by other experimental techniques. An assumption is made in the above instance, that the effective absorptivities of the observed bands are ''very similar'' for the corresponding, yet different, conformational structures.[23] According to Surewicz and Mantsch, studies showed a good correlation ''for about 20 proteins between the secondary structure estimates obtained from X-ray data and IR analysis''.[20,23] They concluded that although the general validity remains to be tested, the assumption appears to be reasonable.[23] Nevertheless, they warn against the use of these estimated percentages as absolute values of the structural contents.

Jakobsen and Wasacz conducted an extensive study of IR spectra–structure correlations of albumin and managed to assign a vibrational assignment for most of the observed bands.[24] Along with the band assignments, they studied the conformational changes upon and during adsorption. Deconvolution was the method they utilized for all spectra, but they based their results on several approaches: past assignments, their own experimental justifications, Raman spectra, and a special software program.[24] This software enabled the researchers to calculate ''the percentage contribution of each amino acid to the intensity at any frequency''. The IR spectra of the 20 amino acids that make up the primary sequence of a protein were used to come up with ''a composite spectrum''. This composite spectrum was based on ''the weight percentage of each amino acid present in the protein''.

There are three main points to be made as summary statements regarding deconvolution. First and foremost, all authors caution against the use of peak heights for quantitative analysis. The process of deconvolution retains peak positions but change the areas and the shapes of the peaks.[1] Therefore, peak heights must not be used for measures of proportions or as indicators of changes.[23] Secondly, although FSD is generally applicable to any spectrum [IR, ultraviolet/visible (UV/VIS), fluorescence, Raman, nuclear magnetic resonance (NMR), etc.], the method must be applied only to bands whose widths are inherently broader than the instrumental resolution.[1,22] Finally, one must take special care in determining the ''resolution enhancement factor''. One needs to choose spectra with high S/N to begin the process and verify to make sure that all the features in the deconvoluted spectra are real. The best way to check is to remeasure the spectrum, if possible, at higher resolution and S/N. If a spectral feature at a lower resolution disappears at higher resolution and S/N, it was most likely an artifact! In other words, it would be wise to confirm the real features by using higher factor values and different apodization functions.

3.4 Multivariate Analysis

In bioanalytical and clinical studies, a researcher is rarely faced with the analysis of a single component. The complexity of biological systems demands multicomponent quantitative analysis. At the same time, the numbers of spectra taken in a typical near-IR or mid-IR experiment could easily number in the hundreds. When combined with the range of the wavelengths, the data points involved quickly become large. However, despite the potentially high information content of FTIR measurements, without a sound analysis technique the qualitative and quantitative information could remain buried. This is why bio/clinical studies using FTIR spectroscopy call for multivariate data analysis. In recent years, mathematical, statistical, database, and expert-system techniques have

come together to be known as *chemometrics*. Multivariate data analysis is a good example of chemometrics applied to the spectroscopic data. At the time it was published (1990), Davies stated that, ''a considerable number of multivariate data analysis methods exist'', and new methods are constantly being developed.[25] In other words, the choice of the method for one's experimental data analysis depends on the software and the particular software parameter selected. An attempt will be made to summarize a few major categories with emphasis on the basic understanding and practical information.

The term ''multivariate analysis'' is often used for analysis dealing with multicomponent data. Most multivariate analysis methods applied to chemical data are based on least squares (LS) techniques.[26] At the same time, all multicomponent spectral analyses are based on the additivity of Beer's law. Therefore, it will be advantageous to grasp a basic understanding of the two ideas, LS techniques and Beer's law.

The additivity of Beer's law may be expressed in the following sequential steps:

1. for a series of components at *a single absorbance* (Equation 8):

$$A(\nu) = \sum a_i(\nu) l c_i \tag{8}$$

   at the i th component of the mixture;
2. for *a range of absorbance* (a spectrum) of a mixture (Equation 9):

$$\mathbf{A}_j = \sum \mathbf{a}_i \mathbf{l} \mathbf{c}_{ji} \tag{9}$$

   where **A**, **a**, **l** and **c** are vector;
3. for *a series of absorbance spectra* with components of linearly independent concentrations (Equation 10):

$$\mathbf{A} = \mathbf{ELC} \tag{10}$$

   where the equation is expressed in a matrix form; **A** = the vector of absorbances, **E** = the matrix of absorptivities, **L** = the vector of pathlengths, and **C** = the vector of concentrations. All vectors and matrices are in bold type.

This expression in matrix form is important because various methods in multicomponent analysis begin with this form. In fact, various quantitative analyses differ only in the ways in which they perform matrix algebra upon the data represented in the above format.

The initial step for the multivariate analysis is the calibration step to obtain the standard spectra. The experimental design must provide for standards with known concentrations of the components of interest. Hence the information regarding **A**, **L**, and **C** is provided by the standards and the values of **E** will be supplied by the calibration. After the calibration has been performed, the concentrations of unknowns can be predicted by measuring the sample absorbances and entering the appropriate values into the calculations.

3.4.1 Least Squares Methods

The use of linear regression is a fundamental and classical approach. When dedicated microcomputers became more readily available, its applications were expanded. Once the basic application of LS techniques to IR spectroscopy was established, both expansion and improvements continued, which resulted in many sophisticated variations. Two approaches involving LS methods will be summarized.

3.4.1.1 Classical Least Squares or **K** *Matrix Method* In the classical least squares (CLS) approach, pathlength and absorptivity matrices are combined into a single matrix called **K**. Therefore, the basic equations are $\mathbf{K} = \mathbf{EL}$ and $\mathbf{A} = \mathbf{KC}$, with the absorbance expressed as a function of the concentration. Taking the **K** matrix, a matrix operation called ''LS fit'' is performed to produce, by definition, ''the best available model of the data''.[1] When **K** has been determined, the unknown concentrations comprising the matrix **C** can be calculated through another matrix operation. The advantage of the **K** matrix method is the relatively straightforward mathematics involved. Also, if so desired, use of this method permits ''an averaging effect'' by use of many standards and wavenumbers in the calibration. There are two basic limitations: (i) its sensitivity to the presence of impurities or unexpected components and (ii) its intolerance of interactions between the sample components. These limitations require, first of all, that the standards do not have any impurities. Also, all components and their concentrations must be known prior to analysis. If impurities are present in the samples, since they must be included in the **K** matrix presentation, researchers must be fully aware of their existence. In other words, one must know the complete chemical composition prior to analysis. This can be a tall order in the case of a complex system such as bio/clinical samples. For these reasons, applications of the **K** matrix work best where the sample compositions are predictable and interactions between components are nonexistent.

3.4.1.2 Inverse Least Squares or **P** *Matrix Method* In the inverse least squares (ILS) method, the original matrix expression $\mathbf{A} = \mathbf{ELC}$ can be rewritten as $\mathbf{C} = \mathbf{PA}$ where $\mathbf{P} = (\mathbf{EL})^{-1}$. In this format, the concentration is a function of absorbance. Therefore, even if the concentration of an impurity is not taken into account, the **P** matrix can be obtained as long as there are as many absorbance measures as there are concentrations. Consequently, with

P matrix operation, the same LS matrix manipulation can be performed successfully with only the concentrations of the known components.

According to Griffiths et al., the **P** matrix can be very time-consuming.[2] One must ensure that there are as many absorbance measurements as components, and these absorbance measurements must be sensitive to changes in concentration. Generally, this means preparing and running many standards. However, not every wavenumber in an entire spectrum can be selected to perform the analysis, and therefore it makes inefficient use of the data.[1] However, in a practical situation, accounting for every component in a sample is difficult. For this reason, the **P** matrix method is often chosen.

3.4.2 Factor Analysis

The aim of the factor-analysis approach is to develop a meaningful mathematical model of the chemical system and use it to predict the properties of test samples.[25] Its major strength is the ability to aid the analyst in isolating the desired information that may be hidden in relatively large amounts of data.[27] Factor analysis is a general technique which has been applied to a wide variety of problems. Apparently, Antoon et al. first applied the factor-analysis approach to IR spectroscopy.[2] As a technique, in addition to factor analysis, the method employs some form of linear regression to reach the final analytical results. The following reasons were listed by Smith for the recent popularity of factor analysis.[1] Factor analysis:

- is insensitive to the presence of impurities;
- makes full use of all spectral data;
- does not require a standard for every wavenumber used;
- helps in identifying the number of components in a mixture;
- can reproduce the spectrum of each component;
- can predict the component concentrations in unknown samples;
- is tolerant of low-quality data.

There are several factor-analysis methods and, in addition, many variations have evolved. Two major types will be introduced: principal component regression (PCR) and partial least squares (PLS) methods. Since these methods are intended for routine, rapid, and nondestructive determination of chemical composition, they are especially suited for clinical analysis.[28] When these methods are employed using computer software, the analysis is performed on the entire spectra with no special requirements for selections of peaks, baselines, etc. As alluded to in the previous section, they may be used when the spectral bands are overlapped or affected by baseline variations, spectral noise, purge variations, sample impurities, and nonlinear response.

3.4.2.1 Principal Component Regression In PCR, prior to the application of the ''regression'' technique, the information content is distilled into a smaller number of *principal components*. Those principal components which correlate strongly with the calibration set of concentration values are used to develop the model system, while those with low correlations are dropped. Hence the method can indicate the errors associated with the prediction and the validity of applying the model.[25]

When the data from the standard spectra are entered, the program will compute the *average* of these spectra. Each standard spectrum is then compared with the *average* spectrum and a new spectrum called a *factor* is calculated. The *factor* describes the difference between the standard and the *average*. The amount of the *factor* in each standard spectrum is called a *score*. Each *score* is multiplied by the *factor*, and the product is subtracted from each standard spectrum. The result of the subtraction is called a *residual*. The *residuals* in turn are used in the next iteration to calculate a new *average* spectrum, a new *factor*, and a new set of *scores*. This is how, each time, the iteration process will strip the spectral contribution of some components from the standard spectra. Using the method described above, factor analysis accounts for the variability in the standard spectra.

The following steps may be incorporated when using PCR as a part of a software program:

1. obtain standard spectra and enter the necessary information regarding the standards into the software;
2. choose the part of the spectrum to be analyzed;
3. determine the optimum number of *factors*;
4. use a process called ''cross-validation'' to test for the optimum number of *factors*;
5. let the software conduct the calibration;
6. measure unknown samples and apply the factor analysis.

It will be wise to keep in mind that the computer program does not know how many *factors* are needed to best describe the data. The iteration will continue until the user stops the process. In fact, several authors point to the determination of the optimum number of *factors* as the key to the use of factor analysis.[1,7,25,27] Some experimentation and practice, in addition to the use of ''cross-validation'', will be required for the best results.

3.4.2.2 Partial Least Squares Method According to McClure et al., the PLS method was developed by Wold et al.[27] PLS differs from PCR in that information contained in both the dependent and independent

variables (absorbance and concentration) plays a role in the development of the calibration model.[1,25,27] Davis also stated that PLS tends to show relevance toward chemical values, since the chemical data are used to find a pattern in the data which correlates with factors.[25]

There are two ways of performing PLS. PLS-1 calculates a separate set of factors and scores for each component whereas PLS-2 calculates one set for the entire data set. Although good software will allow the choice of different factor-analysis methods, it will be advantageous to have some comparative information regarding these methods. The following list was compiled from information noted by several authors:[1,25,27]

- PCR is better known and the easiest of the factor-analysis methods;
- PLS is more accurate than PCR;
- PLS has fewer dimensions, generally, and is easier to interpret;
- PLS-1 is probably more accurate than PLS-2 and works better where the concentrations vary widely;
- PLS-2 takes much less computer time than PLS-1 but gives equivalent results if the concentrations do not vary much.

In a chapter describing the software Computerized Infrared Calculations on Materials (CIRCOM), McClure and Lehmann gave an example of a study of lipids.[27] They analyzed the IR spectra of 21 synthetic mixtures of 14 lipids found in serum. They concluded that the method, which is an offshoot of PCR, made successful predictions for triglycerides, lecithin, sphingomyelin, free cholesterol, and esterified cholesterol. The results for fatty acids were usable for the differentiation of normal and potentially pathological types. They did not feel their results were useful for other lipids included in the study. They remarked that the study was a beginning of ''a more extensive investigation of multiple lipid analysis''.[27] Closer analysis of this example may shed some light regarding the details of PCR method.

Heise and Bittner studied blood substrates in human plasma using PLS.[29] The substrates they chose to study were total protein, glucose, total cholesterol, triglycerides, and urea. Near-IR ATR spectroscopy was utilized. They employed a ''cross-validation'' method to verify the calibration results. This paper with its many references gives a useful description of the development of a multicomponent assay.

The topic of the study conducted by Malins et al.[10] was the linkage of hydroxyl-radical-induced DNA damage with the metastatic state of human breast cancers. The experimental design used the IR spectra in an innovative manner. A three-dimensional plot of principal components from factor analysis was constructed to help visualize the spectral relationship of the cancer and noncancer DNA groups. The authors stated that, ''future research may confirm that principal component analysis (PCA) of FTIR spectra is a promising technique with high structural specificity for discriminating DNA phenotypes in cancer diagnosis and prediction''.[10]

In summary, with the aid of good software, multivariate analysis can be a useful method in handling a large set of complex data. Smith states that ''as long as a physical or chemical property of a sample causes the sample's spectrum to change, the spectral changes and measurements of the property can be correlated''.[1] Furthermore, by simply obtaining their spectra, these properties can be predicted for various experimental samples. Using the above-mentioned multicomponent-analysis methods, one is able to obtain useful predictions from complex bio/clinical data. In general, then, the use of IR spectra can save time and expense in terms of analysis as well as sample preparations.

4 CLINICAL APPLICATIONS

To date, the emergence of IR spectroscopy in clinical chemistry is still in its infancy. The application of this analytical tool to clinical studies and diagnosis has generated a lot of enthusiasm as well as speculation.[30–34] Recently, IR pathology has become increasingly important, since diseases are manifested by changes in the composition of body fluids and tissues, and these changes can be elucidated from the chemical information contained in their IR spectra. Diagnostic applications of IR spectroscopy provide physicians with an objective aid in the identification of the disease state or for staging the disease. This can be achieved with a pattern-recognition approach. Quantitative analysis provides clinically relevant parameters in body fluids which may be used to indicate the metabolic status of the patient. The following applications show that IR spectroscopy has great promise as an accurate and rapid multicomponent analytical technique in clinical chemistry.

4.1 Diagnostic Application

IR spectroscopy has been increasingly applied to the diagnosis of diseases. The initial development was for convenient ways for routine screening and fast diagnosis, e.g. a ^{13}C-labeled urea breath test for screening for *Helicobacter pylori* infection and the diagnosis of liver disease by the detection of $^{13}CO_2$ in exhaled air. More recent developments have involved the combination of visible microscopy and IR spectroscopy in the identification of cancer cells and the elucidation of the possible

Table 4 Examples of diagnostic application of IR spectroscopy

Disease/condition	Analyte	Technique[a]	Refs.
Breast cancer	DNA	Microspectroscopy	10, 35
Breast cancer	Tissues	FEWFTIR	36, 37
Astrocytomas	Protein	Microspectroscopy	38
Cervical lesions/cancer	Tissues, cells	High-pressure FTIR	39, 40
		Microspectroscopy	41
		FTIR	42
Lymphoid tumors	RNA/DNA	Microspectroscopy	43, 44
Drug resistance	Cells	FTIR	45
Biocatalytic activity	Model systems	DRASTIC	46
Metabolite overproduction	Model systems	DRASTIC	46
Skin cancer	Tissues	Fiber-optic ATR	47
Single-cell screening	DNA, proteins, lipids	Synchrotron microspectrometry	48
Bone diseases	Bone samples	Microspectroscopy	49

[a] FEWFTIR, fiber-optic evanescent wave Fourier transform infrared; DRASTIC, diffuse reflectance absorbance spectroscopy taking in chemometrics.

mechanism of the development of cell cancer and the progression of cancer to the metastatic state. Some examples of diagnostic applications are given in Table 4.

4.2 Laboratory Analyses of Pathological Samples

FTIR spectroscopy has been used for fast multicomponent analyses of human blood and other pathological samples. Improvements in analysis are obtained by the adoption of multivariate calibration techniques as described above. For routine blood-serum analysis, it is possible to use a PLS algorithm to calculate the concentrations of cholesterol, triglycerides, glucose, total protein, lipids, urea, and uric acid. In addition to blood serum, other pathological samples have also been analyzed by IR spectroscopy. Fecal fat and fecal carbohydrates can be studied by near-IR reflectance analysis. IR analysis of stool samples is fast and does not require unpopular sample handling. Results indicate that near-IR spectroscopy may be a new, reliable, and accurate test in the diagnosis of carbohydrates and fat malabsorption. Other samples such as gallstones, urinary stones, tissues, bones, and urine have also been analyzed. Selective examples of IR pathological analyses are listed in Table 5.

4.3 Noninvasive In Vivo Monitoring

In vitro monitoring is inherently invasive and the results are often delayed by 1 h or more when the analyses are performed in the central laboratory. The delay may be greatly reduced if the analyses are performed near the patient. In vivo monitoring may be noninvasive and may provide continuous real-time data, but the accuracy sometimes does not match that of in vitro measurements. In vivo monitoring is best applied in the detection of trends of change, and it is used for quantities that change rapidly

Table 5 Examples of pathological samples analyzed by IR spectroscopy

Sample	Analyte	Technique	Refs.
Gallstones	Cholesterol, bilirubinate salt, elements	Microspectroscopy	50–53
Fecal fat	Fat contents	Near-IR	54, 55
Calcified tissues	Minerals	Photoacoustic IR	56
Human adipose tissue	*trans*-Fatty acids	ATR	57
Synovial fluid	Synovial fluid	Near-IR	58
Serum, blood	Multicomponents	Near-IR	58–60
Amniotic fluid	Amniotic fluid	Near-IR	58
Lipase	Lipase	ATR	61
Serum	Multicomponents	Laser excitation IR	62
Biomembranes	Vesicles	Surface-enhanced IR	63
Tissues	Hemoglobin, oxyhemoglobin, cytochrome aa_3, indocyanine green	Near-IR	64
Urine	Urease	FTIR	65
Iliac crest biopsies	Mineral contents	Microspectroscopy	66
Cortical bones	Minerals and matrix	Microspectroscopy	67
Blood	Glucose	FEWFTIR	68
Hair	Drugs	Microscopy	69

Table 6 Examples of non-invasive in vivo monitoring by IR spectroscopy

Sample	Analyte	Refs.
Blood (through skin)	Glucose	70–77
Tissue, muscle	Oxygen	78–86
Blood (through skin)	Hemoglobin	74–76, 79, 87–90
Tissue, muscle	Hemoglobin, oxyhemoglobin	74–76, 85, 87, 90, 91
Brain/cerebral	Hemoglobin, oxyhemoglobin	88, 89, 92, 93
Blood (through skin)	Urea, cholesterol	76, 89
Blood (through skin)	Albumin, proteins	76, 89, 94
Muscle	Phosphocreatine	82
Muscle	Glycolytic metabolites	95
Mammalian fluids	Nitric oxide	96
Tissue, blood	pH	97, 98

and unpredictably and where a suitable therapeutic action is available. Near-IR spectroscopy is normally used for monitoring. Examples of noninvasive in vivo monitoring include oxy- and deoxyhemoglobin in the brain, blood glucose, bilirubin, albumin, urea, cholesterol, tissue oxygenation, cerebral circulation, and oxygen metabolism during surgery, cerebral blood volume, and cytochrome oxidase. Examples of these are listed in Table 6.

4.4 Monitoring of Drug/Medicine Metabolism

IR spectroscopy is used routinely for the identification and structural determination of new pharmaceutical compounds (Table 7). A new application of IR spectroscopy in clinical chemistry is for the monitoring of drug/medicine metabolism in the body. It can be used to determine the concentration of drugs and the metabolites in body fluids or body parts, e.g. hair. A breath test has also been used with an isotopically labeled drug to determine the concentration of a metabolite of the drug. The concentration of the metabolite is then used to determined the rate of metabolism of the drug. The effects of drugs in vitro can also be monitored by the changes in cell viability after treatment with drug using FTIR microspectroscopy. Ex vivo drug response, sensitivity, or resistance to drugs can be predicted from the IR spectra of the diseased cells before and after treatment of the patients with the drugs.

5 FUTURE PROSPECTS

Future prospects for application of various FTIR experimental techniques in bioanalytical/clinical studies appear to have at least two main possibilities.

The first possibility is the study of protein and DNA secondary structural analysis. Until recently, although IR spectroscopy was recognized as a potentially useful method, several major limitations interfered with its

Table 7 Examples of monitoring of drug/medicine metabolism by IR spectroscopy

Drug/medicine	Methodology	Refs.
Various medicaments	Noninvasive IR detection of the medicine, metabolites, or markers (patent)	99
Drugs administered by transdermal delivery	Noninvasive quantification by IR of diffusing species (e.g. salicylic acid) through artificial neural network (research model)	100
Drugs detectable in hair	Probe of longitudinal sections of hair along growth line for time measurement; probe of cross-sections to review hydrophobic/hydrophilic characteristics of drug by IR microspectroscopy (clinical)	101
Isotopically labeled drugs	Detection of isotopically labelled carbon dioxide or other metabolites in the breath for rate of metabolism (clinical)	102
Tetracycline	Tracking of rate of release from local drug delivery system consisting of poly(lactide-co-glycolide) films (research)	103
Bryostatin 1,2-chlorodeoxyadenosine	Detection of cell membrane changes as basis of predicting ex vivo drug response (sensitivity/resistance) (preclinical)	104–106
Indomethacin, ibuprofen	Detection of effects on cerebral perfusion and oxygenation of intravenous ibuprofen and indomethacin treatment in preterm infants by noninvasive near-IR spectroscopy (clinical)	107
Propofol (an anesthetic drug)	Study of magnesium–propofol interaction in vitro as related to fluctuations of Mg in serum after clinical administration of propofol (research)	108
Adamantyl maleimide	Study of conformational changes in gastric carcinoma cell membrane protein after treatment by microspectroscopy (research)	109

application to studies of protein conformation. With the introduction of the powerful, computerized FTIR instrumentation, the improvement of the S/N and the availability of extensive data manipulation became a reality.[110] When these new developments are coupled with sophisticated methods of analysis, the use of FTIR spectroscopy may present several definite advantages. Unfortunately, so-called classical methods of protein and DNA structural analysis have known limitations. Even when crystals of high quality are available, the crystallographic analysis gives static information. CD spectroscopy used in connection with the study of secondary structure addresses proteins in aqueous solution but may not be suitable for the lipid environment.[111] To understand better the conformational changes, studies of protein must involve investigations in different environments, under physiological and nonphysiological conditions. FTIR spectroscopy allows the easy detection of structural changes with samples in water, organic solvents, lipids, and solid films with reasonable requirements for sample preparation. Furthermore, the results obtained will be dynamic in nature. As these changes are documented quantitatively, use of the spectral manipulations such as derivatives and deconvolution may permit further investigations of the breakdown of components (e.g. α-helix and β-turns). In addition, FTIR difference spectroscopy and the use of FTIR with ATR can increase detection capabilities. Hand in hand with the new growth in the information content regarding proteins and DNA, it is reasonable to expect further expansion in the use of FTIR methods in the area of structural analysis.

The second area of possible future growth is clinical/medical diagnostics and prediction research. Admittedly, use of FTIR spectroscopy in this area is a new venture. Recently, however, many examples can be found in various professional journals. They utilize a full complement of multicomponent analysis with computer software. Many researchers skillfully manipulate the experimental designs to analyze chemical changes under various environmental and bio/medical conditions. Studies involving substrates in various body fluids are one of these groups. Effective comparisons can be made, for example, of blood samples in dried film with that of the liquid form. The second group of research involves work on the analysis of diseased bio-samples. The pioneering work of Malins et al.,[10] for instance, shows interesting future possibilities.

The ease and speed of analysis and the sample preparation and measurements using FTIR spectroscopy have not been fully utilized. With proper consideration of innovative experimental designs, the possibilities for the use of FTIR spectroscopy plus computerized analysis are wide open. The challenge awaiting researchers is to continue to work to build on the groundwork, which will extend the powerful physical method of FTIR spectroscopy from the chemistry laboratory into the biochemical and clinical settings.

ABBREVIATIONS AND ACRONYMS

ATR	Attenuated Total Reflection
CD	Circular Dichroism
CIRCOM	Computerized Infrared Calculations on Materials
CLS	Classical Least Squares
DRASTIC	Diffuse Reflectance Absorbance Spectroscopy Taking in Chemometrics

In the last 40–45 years, instruments have evolved from simple analyzers that analyze few analytes in an hour to auto analyzers that analyze hundreds of tests in a fraction of an hour. A historical perspective on the evolution of the instruments, with discussion on the basic principles of their operation, along with the advantages and limitations of methodologies, is provided. Information on standardization, quality control and quality assurance in the clinical laboratory is also included. The article concludes with a brief discussion on the future developments in instrumentation. The material presented in this article is meant as a reference. For detailed information the reader is referred to other books and publications.

1 INTRODUCTION

In the last 40–45 years there has been tremendous evolution in clinical laboratory instruments. Instruments have evolved from simple analyzers that would analyze one or two analytes in an hour to autoanalyzers that analyze hundreds of tests in a fraction of an hour. This evolution has been brought about by greater utilization and dependence on clinical laboratories in the treatment of disease. Clinical laboratory instruments have evolved to keep pace with greater demand and reliance on laboratory data. Not only has there been an increase in the request for routine tests, but with the advance of medicine there has been an increase in the menu of clinical diagnostic tests available. Many of these changes have been brought about by changes in the health care industry. With managed care and cost reduction the face of clinical laboratory is changing rapidly. Rapid changes are also taking place in industry that manufacture these instruments and autoanalyzers. Acquisitions and mergers of companies have become common and therefore names of instruments and companies that manufacture them may have changed from the ones that laboratory professionals have been familiar with. Much of the work done in the clinical laboratory has been in the area of clinical chemistry; therefore the clinical chemistry section of the laboratory has seen the most rapid growth in instrumentation and automation.

An overall perspective on the principles of laboratory instruments is presented here. The article begins with

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

a historical perspective. It is interesting to note that although a major evolution of laboratory instruments has taken place in the last 40–45 years, rudimentary instrumentation in some form has existed for over a century. The historical perspective section ends with the current status of instruments in the laboratory. The next section covers the basic principles and the major components of instruments. The instruments discussed range from spectral methods to those that employ nuclear radiation, with advantages and or limitations discussed in the following section. The other topics that follow are standardization, quality control and assurance. The article ends with a discussion on future developments in instrumentation.

It is hoped that the information provided here on the principles of clinical laboratory instrument in clinical chemistry will be found useful by all professionals working, not only in the clinical laboratory setting but also by academics in the teaching profession and other professionals in physicians' office laboratories. The information is given in a simple, concise manner without resorting to details which would be beyond the intended scope. The material presented here is meant as a reference. For detailed information the reader is referred to other books and publications.

2 HISTORICAL PERSPECTIVE

The field of clinical chemistry involves analysis of chemicals present in body fluids and tissues to diagnose disease. The field may date back more than 2000 years when the Hindu physician Sasruta reported the presence of ants around urine, an indication of the presence of sugar in urine. During that period diagnosis was based on inferences from observation.

This field of clinical chemistry, a part of diagnostic laboratory medicine, has evolved not only from various branches of chemistry, especially analytical chemistry; but also from other areas of sciences, such as physics, mathematics, physiology and biology. Therefore a comprehensive historical perspective would truly involve historical landmarks of various branches of science, which would be beyond the scope of this section. Nevertheless certain salient contributions specific to the field are worth noting. Historical perspective, provides us with an insight of the past and the future directions we are headed in.

2.1 Spectral Instruments

The earliest clinical laboratory instruments were based on the measurement of color formed when a body fluid under examination was made to react with a reagent. The intensity of color formed was proportional to the quantity of chemical in the examination fluid. These instruments were named colorimeters based on their ability to compare or measure color with that of similar solution of known strength. A working manual of clinical pathology by Todd named *Clinical Diagnosis by Laboratory Methods* was first published in 1908 and underwent several revisions. It describes the colorimeteric methods and the early colorimeter instruments in the July 1925 edition.[1]

During that period the Duboscq type of colorimeter, the Kober and certain others manufactured in the USA were considered satisfactory. Color match between the unknown solution and the standard solution was achieved by either raising or lowering the glass bottomed cups of solution in which glass plungers were immersed to observe the color match viewed through a single field. Other types of colorimeter that were used during that period and are mentioned in the July 1925 edition are the Bock–Benedict, the Hellige and the Denison colorimeters working on general principles similar to that of the Duboscq. All of these instruments required good eyesight for observation.

The colorimeters of the late nineteenth century underwent several evolutions and modifications brought about by availability of new tests and techniques. During the 1940–1950 period many of these tests were conducted at the laboratories of Otto Folin, Michael Somogyi and D.D. Van Slyke using simple photometers. These simple photometers are today's sophisticated spectrophotometers that employ the principle of light in the measurement of the body fluid analytes. In 1940 Arnold Beckman contributed to the development of the DU spectrophotometer that was introduced at that time. The Beckman model DU-2 ultraviolet (UV) spectrophotometer was an extensively revised version of the pioneer model DU. This instrument was regarded over the years as the authoritative instrument in the rapidly expanding field of UV spectrophotometry. It facilitated such studies as fluorescence, reflectance, flame emission, reaction rate, enzyme kinetics, microanalysis and column chromatography. This was made possible by a wide selection of accessories for the instrument.[2] Other clinical laboratory spectrophotometers were developed between late 1950 and 1960. The Gilford Stasar III evolved from Gilford 300N that was introduced in the late 1960s. The Bausch and Lomb Spectronic 100 was introduced in 1970. The earlier model was Spectronic 21.[3] Nephelometers were developed later in the 1960s.

The atomic absorption (AA) spectrophotometer, used in the analysis of trace metal, was introduced in the middle to late 1950. Its application has grown steadily since then. Perkin-Elmer Corp. was among the first to offer microprocessor-based analytical instruments. In 1975, Perkin-Elmer introduced the model 460 AA

spectrophotometer. In 1978 Perkin-Elmer pioneered the infrared Data Station concept, and in 1981 the Laboratory Information Management Systems LIMS/2000 series was introduced.[4]

In the middle to late 1950s other instruments were developed by companies based on emission of radiant energy. The Coleman flame photometer model 21 developed by the Coleman Division of the Perkin-Elmer Corporation was common in many clinical laboratories. This model was later replaced by model 51, with automatic igniter. Instrumentation Laboratories introduced model 143 that was later replaced by an improved version model 343. Other flame photometers were the Turner model 510 and the Kina Flame System by Beckman Instruments Incorporation. Although the phenomenon of fluorescence, phosphorescence and chemiluminescence was discovered earlier, fluorometers were only introduced in the middle to late 1950s.The earlier fluorometer models were Coleman 12C by Perkin-Elmer, and Turner model 111 by G.K. Turner Associates. Many of the earlier versions were bulky and had some limitations and were later modified or replaced with more compact models.

2.2 History of Electrochemical Methods

The need for more compact and maintenance-free instruments that were also very sensitive and specific for analysis of microanalytes revolutionized the field of clinical laboratory investigation. Advances in the field of microchemistry are credited to Samuel Natelson. Potentiometric measurements using glass electrodes were applied to pH determination prior to 1920.[5] In 1905 Cremer discovered that two solutions of different hydrogen concentration separated by a thin glass membrane produced a potential that was proportional to the difference in hydrogen ion concentration on either side of the membrane. Cremer's discovery led to the development of the first glass electrode by Haber and Klemensiewicz in 1909.[6] One of the first pH meters developed for laboratory use was the Beckman model G pH meter. Other companies on the market were Orion Research Inc., Radiometer, Instrument Laboratories, Corning Scientific Instruments, and Coleman Instruments Division, Perkin-Elmer. The development of ion-selective electrode (ISE) technology is due mainly to advancements made in the area of potentiometry and electronics. With the development of microprocessors, and further developments in potentiometry, ISE technology became an established procedure in the clinical laboratory for electrolyte testing. The focus shifted from measuring ion concentration to measuring ion activity and many different electrodes began to be developed for measuring various analytes including blood gases and enzymes. Stow and Randall[7] were the first to record measurement of the partial pressure of carbon dioxide, P_{CO_2}, by P_{CO_2} electrode. The present-day P_{CO_2} electrode is developed from the earlier work of Severinghaus and Bradley.[8]

In the late 1950s, Poul Astrup contributed to the measurement of blood gases and pH using capillary electrodes. Later, Beckman Instruments introduced a blood pH measuring system. In the 1970s measurements of sodium, potassium, chloride, and ionized calcium by ISE became routine laboratory procedures. ISE methodology was applied to the determination of many electrolytes and other analytes. In fact the field of electrochemistry had began much earlier in the nineteenth century. Michael Faraday's contribution – Faraday's laws of electrolysis – has a direct application to coulometry. The measurement of chlorides in biological samples is an extension of the electrolyte measurement methods developed by Zall et al.[9] Later, Cotlove[10] applied the principle of coulometry to the determination of chloride, using a silver electrode. In the 1960s the principles of polarography and amperometry were applied to developing electrodes that could sense oxygen consumption. The Beckman Automated Stat/Routine Analyzer (ASTRA) Systems employed the oxygen sensing electrode for glucose determination. This P_{O_2} polarographic electrode, also known as the Clark electrode, is used in the recent Beckman ASTRA CX 7 and 9 systems.

2.3 History of Separation Techniques

The separation techniques of chromatography and electrophoresis date back to the early twentieth century when the Russian botanist, Tswett, in 1906 was working on separating plant pigments, thus yielding the name chromatography for the separation of the pigments. In 1952 James and Martin developed gas–liquid chromatography (GLC). In 1965 Cawley,[11] published the ''Principles of Chromatography'' in a manual for a workshop in chromatography. In the early 1970s advances in chromatography and microprocessor-aided computer technology have led to the more efficient technique of high-performance liquid chromatography (HPLC). Several HPLC systems and detectors are available.[12] Although liquid chromatography (LC) was discovered before gas chromatography (GC), its use in the clinical laboratory was limited. With the development of small (10 μm) totally porous particles in the early 1970s, LC's applications for clinical laboratory use gained popularity over GC.

Tiselius in 1937 first devised the free solution or moving boundary method for the study of proteins by electrophoresis. Although the technique is still used in research, it is not used in clinical laboratories for routine work. Because of the limited resolution of serum proteins by paper, cellulose acetate and agarose gel, polyacrylamide gel electrophoresis (PAGE) is a

popular choice for the separation of serum proteins. Applications of electrophoresis for better resolution and sharper identification of protein patterns, have been seen in techniques including isoelectric focusing (IEF), and capillary electrophoresis (CE). In the 1970s Corning and Helena electrophoresis systems were quite popular. Later, Helena Laboratories developed the rapid electrophoresis system for automated electrophoresis. Based on the pioneering work of Hjerten, Jorgensen and Lukas, Mikkers, Terabe, and Cohen and Karger, different modes of capillary electrophoretic separations were developed.[13] In contrast to traditional electrophoresis, CE is well suited for automation.

Instruments based on the measurement of nuclear radiation date back to the period when Geiger-Müller counters were the first to be used in the clinical nuclear medicine laboratory in the late 1930s. Most of the instruments in a clinical chemistry laboratory employ scintillation detectors to measure γ-radiation, emitted by radioactive substances.

2.4 History of Automation

Automation in the clinical laboratory was the result of an increase in demand for diagnostic tests and as a result of development of microprocessors and computer-aided technology. During the 1950s, Leonard Skeggs of Technicon Inc. developed and introduced the continuous flow system for the analysis of routine chemistries. Initially these were single channel autoanalyzers that would perform one single test. By the mid 1960s multichannel autoanalyzers were available that would perform a number of profiles. Technicon introduced SMA 6/60 and SMA 12/60 sequential multiple analyzers that would perform six or 12 parameters on one sample and would process a number of samples in 1 hour. The evolution of this continuous flow technology from single and dual channel analyzers had a significant impact on clinical laboratory operations and became the yardstick for measuring the performance of any new instrumentation for the clinical laboratory. In 1981 Technicon introduced SMAC II, its top-of-the-range, high-volume chemistry analyzer, which succeeded the earlier model SMAC (sequential multiple analyzer with computer). The SMAC II instrument had the capability of analyzing 20 chemistries at the rate of 150 samples per hour. In the late 1960s due to rapid advancement in electronic solid-state transistors, printed circuit boards replaced vacuum tubes in instruments, and this revolutionized troubleshooting of instruments. At the first Oak Ridge conference in 1968, instruments based on centrifugal analysis were presented. In the 1970s, centrifugal analyzers assumed a pivotal role in the automated clinical laboratories. With improvements in on-board microprocessors and minicomputers, coupled with the development of new assay procedures, these instruments became increasingly more flexible in handling the growing volume and diversity of laboratory determinations.[14] Roto Chem by American Instruments, GEMSAEC by Electro-Nucleonics and CentrifiChem by Union Carbide were the early centrifugal analyzers on the market. Many of the earlier centrifugal analyzers were batch analyzers, that is they ran the same test or tests on the same sample in one run. Random access analyzers that were soon to follow in 1980s, provided more flexibility in sample testing from a menu of over 20 tests. Random access analyzers, however, utilized more time in programming the analyzer for particular tests requested for analysis. Later on, bar coding of the samples alleviated the problems. These analyzers had a very high output of tests per hour. Eastman Kodak introduced in 1981 the Kodak Ektachem system that had the capability of random access as well as discrete analysis using dry slide technology. From a menu of tests available on a cathode ray tube (CRT) monitor, tests were selected. Many hybrid autoanalyzers of random access and discrete analysis have been on the market since the 1980s: the Coulter DACOS, the Cooper DEMAND, the Hitachi 705, the Beckman ASTRA, the Du Pont Aca, the Roche Cobas Bio, Technicon RA-1000 are just a few examples.

3 SAMPLE REQUIREMENT AND PREPARATION FOR ANALYSIS

Collection and preparation of samples for analysis require careful attention to various factors. An important factor for consideration is the diagnostic laboratory test for which the sample is to be collected. The diagnostic test will determine the nature of the specimen, collection time, fasting or nonfasting state, and the nutritional status of the patient. Depending on the diagnostic test, the type of vacutainer tube or the collection system required should be considered. The diagnostic test may also determine length of time before a sample is analyzed. Preanalytical and analytical temperature of the specimen, exposure of specimen to light or air immediately after collection, the volume of specimen needed, disinfectant for venipuncture site, and the site of collection are some other factors that depend on the type of diagnostic test. For detailed reviews of biological and preanalytical variables refer to Young[15,16] and Ladenson.[17] Blood is the most common specimen analyzed in the clinical chemistry laboratory. Certain chemicals may be drastically affected by hemolysis. It is important that plasma or serum be separated from cells as soon as possible but certainly within 2 h.[18] Urine samples although common are not as frequently analyzed for chemistries as blood. At times

other body fluids, such as spinal fluids and gastric contents, may also be analyzed. Proper identification of the sample is crucial.

Winsten[19] describes the methods for collection and preservation of specimens for clinical chemistry. With the exception of glucose, triglycerides and inorganic phosphorus most blood constituents reveal no significant change after a standard breakfast, so it is not essential for the patient to be in an absolute fasting state prior to blood specimen collection.[20] Lipemia caused by chylomicrons from transient increase in triglycerides from meals containing fat however can interfere with many chemical analyses because of turbidity. Therefore, blood should be collected in the postabsorptive state, usually after an overnight fast of 12–14 h. This is critical for lipid analysis. The National Committee for Clinical Laboratory Standards (NCCLS) gives procedures for the collection of diagnostic blood specimens by venipuncture and provides further information for the collection of specimens.[21] The proper procedure for collecting blood from infants is described in the NCCLS standard H4-A3.[22] The proper technique for arterial puncture is described in NCCLS standard H11-A2.[23] For further reading on specimen collection and processing refer to Young and Bermes.[24]

4 DISCUSSION OF PRINCIPLES OF INSTRUMENTS AND THEIR MAJOR COMPONENTS

4.1 Instruments Based on Molecular Absorption Spectroscopy

Instruments that employ radiant energy in the measurement of analyte are based on either the absorbance, emission, reflectance or scattering of the radiant energy. These instruments employ visible light or UV light of the electromagnetic spectrum in the quantitation of the analyte. Instruments that employ the absorbance of radiant energy are colorimeters, photometers, spectrophotometers and UV spectrophotometers.

The term colorimeter refers to the measurement of colors. The term and the instrument are obsolete in the modern clinical laboratory. These are simple instruments that lack specificity and sensitivity in measuring analyte. The instruments employ light from a tungsten filament lamp usually passing through a simple glass filter, for a chosen wavelength. The glass filters remove all other wavelengths from the white light of the tungsten filament lamp, except one particular band that is the color of the glass filter that it passes through. This band passes through the cuvette which holds the colored solution. Depending on the intensity of the colored solution, the band of light incident on the cuvette is absorbed and the rest is transmitted. The transmitted light falls on a photodetector, which converts the light into electrical energy. The output of the electrical energy is in proportion to the amount of light transmitted after absorbance by the colored solution in the cuvette. The electrical energy passes through a meter which makes a needle move on a scale of absorbance or transmittance readings, or the electrical energy may be converted to a digital readout of transmittance, absorbance or concentration.

The term photometer literally means measurement of light. In the clinical laboratory the term is used in a generic sense as an instrument that measures light. The instrument is similar to a colorimeter and works on the same principle.

Spectrophotometers are instruments that utilize a single narrow band of the spectrum of white light to pass through a solution in a cuvette. The solution in the cuvette is the one in which the analyte from the sample to be analyzed has reacted with a reagent. The main components of a spectrophotometer are a tungsten filament lamp as the light source, entrance and exit slits with associated optics, a monochromator, the detector, and the meter or readout device and the printer or the recorder. The quality of a spectrophotometer depends chiefly on the monochromator and the detector. The monochromator is a device that isolates a single narrow band of wavelength from the spectrum of white light of the tungsten filament lamp. The narrower the band of wavelength the better is the quality of the instrument. In the specifications of instruments this is given as the bandwidth or bandpass. The quality of the spectrophotometer, and therefore its cost, depends on the type of monochromator. Monochromators are usually prisms or gratings. Simple glass filters or interference glass filters are usually found in photometers or colorimeters. High-quality prisms are used in very sophisticated models of spectrophotometers. The quality of prisms adds to the specificity and the sensitivity of the instrument and therefore to its cost. Grating monochromators provide better resolution of the wavelength than prisms, but this depends on the blaze angle of the grating. The detectors are phototubes or photomultiplier tubes that convert the light energy into electrical energy. A phototube consists of a photosensitive cathode on which the transmitted light from the cuvette falls. When the transmitted light from the cuvette strikes the photosensitive cathode, electrons are ejected which are then captured on the anode. Thus, light is converted into electrical energy. Spectrophotometers are designed as either single or double beam instruments. Single beam spectrophotometers have a single optical path from the light source to the detector. In the double beam instruments, light passes through the sample as well as a reagent or water blank (reference beam). This compensates for line voltage fluctuation or any other variation in light source intensity which may otherwise affect

the readings. The double beam spectrophotometers are either with single detectors or double detectors. The ones with single detectors (double-beam-in-time) are equipped with either a rotating chopper or a mirror that alternately focuses the sample and the reference beam on the detector. The ones with two detectors (double-beam-in-space) have the isolated beam from the monochromator split by half mirrors. The double beam spectrophotometers are equipped to continuously monitor absorbance against time (kinetic measurements) or absorbance over a range of wavelengths. The absorbance of the blank is automatically subtracted. Advances in technology have provided truly monochromatic light beams by means of tunable lasers, ultrafast scanning spectrophotometers and extremely sensitive photodiodes. The Beckman DU-70 scanning spectrophotometer is an example of a highly sophisticated model. It has a UV range as low as 200 nm with a fixed 2 nm bandpass. This computerized model has a high resolution graphic video display. The spectral data are displayed in transmittance and absorbance. In UV spectrophotometry, hydrogen and deuterium lamps are used to provide continuous spectra in the UV range. As UV light is strongly absorbed by lime glass, quartz cuvettes must be used.

4.2 Performance Parameters for Spectrophotometric Techniques and Wavelength Calibration

In quantitating the analyte, the absorbance of the unknown is usually compared to the absorbance of a standard (calibrator). Thus minor errors in wavelength calibration, variation in spectral bandwidths, presence of *stray light*, etc. do not usually contribute to serious errors. Using a series of standards (calibrators over a wide range) also provides a check for linearity, and therefore agreement with Beer's law for a particular procedure and instrument. When calculating the analyte, with previously determined or published values for molar absorptivities or absorption coefficients, e.g. in enzyme assays using NAD–NADH (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide reduced form) reactions, the instrument needs to be checked more thoroughly for photolinearity and wavelength calibrations. Performance verification of spectrophotometers on a periodic basis also improves reliability of routine analysis. When wavelength calibrations are performed on narrow spectral bandwidth instruments, holmium oxide may be used as calibrator over a range of 280–650 nm. With broader-band pass instruments, a didymium filter may be used. A solution of potassium salt may also be used in performing wavelength calibration and photometric accuracy checks. For details regarding standards in absorption spectrometry see Burgess and Knowles.[25] Standard Reference Materials (SRM) available from the National Institute of Standards and Technology (NIST) for calibrating and verifying spectrophotometric and fluorometric measurements are published in the NIST SRM catalog.[26]

4.3 Reflectance Photometry

Reflectance photometry involves measurement of the reflected radiant energy. This technique is applied by Eastman Kodak to its Kodak Ektachem 700 series analyzer. Dry reagents are impregnated on to thin layers of plastic film and mounted in a slide. A drop of the specimen applied on the slide allows the analyte to react with the reagent to produce a color. This color can be measured by reflectance photometry. As with spectrophotometric methods, the color produced is proportional to the analyte present in the specimen. The autoanalyzer section details the instrumentation and slide technology.

4.4 Nephelometry

Nephelometry involves measurement of light scattered by particles. The amount of light measured is proportional to the amount of particles in solution. Simply, the instrument involves a lamp, optics to include a lens, the cuvette containing the sample and detector. The source of radiation may be either the helium–neon laser, quartz–halide lamp or the xenon lamp. Nephelometry is widely used in the measurement of antigen–antibody complexes. Another application is in the measurement of enzymes that act on particulate substrate. The Coleman amylase/lipase analyzer is a nephelometer that is used in the measurement of the enzymes amylase and lipase. When the enzymes act on the substrate the loss in turbidity can be measured. The loss in turbidity is in proportion to the enzyme present. Nephelometry has been applied in immunological work. For comparisons of features of various immunonephelometers see Nalesnik et al.[27]

4.5 Atomic Absorption Spectrophotometry

AA spectrophotometers are used in clinical laboratories for the measurement of metals such as calcium, magnesium, copper, lead, zinc, mercury and several other trace metals. The principle of this instrument involves maintaining the atoms of the element being analyzed in the ground state, so that these atoms are able to absorb light of a specific wavelength. This specific wavelength that the atoms can absorb corresponds to the wavelength the atoms would emit if they were excited. The amount of light absorbed is proportional to the analyte in question. The atoms of the analyte, however, need to be dissociated from their chemical bonds. This dissociation is achieved by heat of flame or furnace. A hollow cathode lamp made

from the metal in question is employed to produce a very specific wavelength that the atom of the element to be analyzed will absorb. The lamp is a neon or argon lamp with the cathode made from the metal in question. In disassociating of the atom from its chemical bonds, some emission occurs, but the percentage is small. With an efficient atomization technique, it is possible to maintain a large population of atoms in the ground state. The components of the instrument are a hollow cathode lamp, a chopper, an atomizer burner, a monochromator, a detector and a readout device. A hollow cathode lamp is available for many metallic elements. A hollow cathode lamp is adequate for most elements. For volatile elements, electrodeless discharge lamps are available. For determination of alkali metals (rubidium, cesium, sodium, potassium) and other elements (zinc, cadmium, mercury) a vapor discharge lamp is preferred.[28] For most metals, an air/acetylene flame which reaches a temperature of 2400 °C, is adequate for atomization. However, certain metals (aluminum, tin) require higher flame temperature which can be achieved by a nitrous oxide/acetylene flame. The atomization of elements that require high temperature can be achieved by raising the temperature of the flame, but it is likely that the population of neutral atoms available for absorption will be reduced because of ionization. Atomization of the element also depends on the design of the nebulizer/burner assembly. There are two types of burners, the premix and the direct consumption burner. Each has its advantages and disadvantages. One of the disadvantages of the premix nebulizer/burner design is the large sample size that is needed to compensate for dilution before aspiration and the fact that a small percentage (about 10%) of the aspirated sample reaches the flame. This limits the sensitivity of trace elements in biological fluids.[28] In this respect the direct consumption burner has an advantage in that it eliminates sample waste.

Although the direct consumption burner design eliminates the sample waste problems, the samples are still subject to dilution by flame gases thereby affecting the sensitivity of determination. The flameless systems avoid the dilution effects of the flame and also eliminate the separate sample preparation steps required in flame systems. Graphite systems have been widely used in place of flame systems. In the graphite system high temperatures can be attained to volatilize matrix constituents of the sample with minimum volatilization of the sample. As in spectrophotometers, both single beam and double beam designs are available. Matrix interference due to sample viscosity problems can be overcome by making the standards in the same matrix as that of the sample. Chemical interference occurs when thermally stable compounds do not readily disassociate into neutral atoms, as in the case of calcium and magnesium forming stable complexes with phosphate. In this case, excess lanthanum or strontium is added to tie up the phosphate and release calcium and magnesium for measurement. Analysis of serum or plasma is done after appropriate dilution with buffer in the flame system or without pretreatment in the graphite system. Metals bound to proteins can be released by treating the sample with trichloroacetic acid. The metal is then chelated in a protein-free filtrate by a chelating agent, and after adjustment of pH, extracted in an organic solvent such as methyl isobutyl ketone before measurement. AA has wide applications in the measurement of lead, cadmium, arsenic in toxicology and selenium, manganese, zinc and other trace elements in nutrition.

4.6 Emission Flame Photometry

The flame photometry technique of measuring sodium, potassium, calcium and lithium is being rapidly replaced by ISE technology. Many laboratories still use flame photometry for electrolyte determination. Flame photometry involves measurement of emission spectra produced when a metal is ignited in a flame. The spectra are characteristic of the element being measured. When an atom of an element absorbs energy, the outer electrons move to a higher orbit (unsteady state); the electrons return to the ground state and in so doing emit the absorbed energy as light. The light that is emitted is characteristic of the element in question. Flame photometry can only be applied to measure easily excitable atoms. The components of the instrument are the burner assembly, optics including the lens and exit slit, the monochromator and the detector. There is a monochromator and a detector for each analyte, i.e sodium has its own filter and detector, as does potassium. The detector is usually a photomultiplier tube to detect even the weak signals from the flame. The burner assembly, as seen in AA spectrophotometry, is the direct consumption or the premix assembly. The advantages or disadvantages of the two types of burner assembly are similar to the ones seen in AA spectrophotometry. The fuel content of the gas and the pressure and composition of the gas mixture are critical for the proper configuration of the flame. The blue inner cone portion of the flame is the hottest and atoms absorb energy in this zone. Light from the element is emitted in the outer portion of the flame. Compressed air used to support combustion may contain moisture and can pose a serious problem in the element being ignited.

4.7 Use of Internal Standard in Flame Photometry

In order to compensate for flame fluctuation, an internal standard, usually lithium, is aspirated along with the sample. The emission peak of the internal standard should be very different from the emission peak of the sample. This enables the two spectra to be distinguished readily by the detector. In cases where lithium is present in

the biological sample, another internal standard such as cesium should be used. The criteria for the internal standard are that its concentration should be the same in the sample being analyzed as in the calibration standard. The excitation potential of the internal standard should be similar to that of the analyte being measured. The emission spectra of the internal standard should be distinct from the emission spectra of the sample being analyzed. The internal standard should not be present in the biological fluid of the patient.

4.8 Molecular Emission Spectroscopy–Fluorimetry

Certain substances have the ability to absorb short waves (UV light) and convert them to longer wavelengths, or visible light; these substances are said to fluoresce and the phenomenon is known as fluorescence. Fluorimetric techniques not only provide increased analytical sensitivity but also have wider applications in flow cytometry and fluorescence microscopy. There are many compounds of biomedical importance that can be determined by fluorescent spectroscopy. As with spectrophotometers, fluorimeters are designed as single beam or double beam instruments. The main component of a single beam spectrophotometer is the light source which produces UV light. The optics include the lens, the primary filter and the secondary filter. The secondary filter is at right angles to the sample cuvette. The detector that is in line with the secondary filter is a photomultiplier tube. The light source is usually a mercury or xenon lamp; both lamps carry high intensity. Mercury lamps are not effective at wavelengths below 250 nm. Xenon lamps, although expensive, provide a wider range of wavelengths in the UV and visible regions. As UV light is absorbed by glass, the lamp envelope and other optics are of quartz. The primary filter allows only excitation energy (high energy or short waves) to fall on the sample cuvette. This enhances the specificity for the analyte in question by avoiding any other interfering substances from excitation. It also avoids photodecomposition of the analyte due to unwanted radiation falling on the sample. The secondary filter allows only the fluorescent or emitted, longer waves to fall on the detector. The detector serves the same purpose as in spectrophotometers. Fluorescent units are read off the dial or from a digital readout. The double beam fluorimeters have the same advantages as with other double beam design instruments.

Although fluorescent spectrophotometry is a very sensitive technique and can detect concentrations up to $1\,\mu g\,L^{-1}$ and is ideal to measure low concentrations of analytes, several factors need to be taken into consideration when working at very low concentrations: glassware can adsorb the analyte onto its surface and pose problems; quenching is another problem; and trace contaminants in solutions can suppress fluorescence. Also, it is important to adjust the pH of the solutions exactly, as slight changes in pH can affect the readings.

4.9 Electrochemistry

Electrochemistry has a wide application in industry. In a diagnostic clinical laboratory, electrochemistry involves the application of chemistry and electricity principles to the measurement of analytes. Based on a chemical reaction of an analyte an electrical signal is produced. This electrical signal can be determined, and can then be related to the concentration of the analyte. When a metal electrode is placed in a solution of its ions, a potential exists at the interface junction of the metal electrode and its solution. The solution containing the metal electrode may be considered as a half-cell. If this half-cell is connected by an electrical conductor to another half-cell of a constant potential, then the potential difference between the two half-cells can be measured and related to the concentration of the ions in the first cell. *Potentiometry*, that is the measurement of potential between two cells in which a chemical reaction takes place, utilizes this principle in measuring the concentrations of analytes. In practice, the electrode potential of one half-cell is kept at constant potential. The electrode potential at the other half-cell varies based on the concentration of ions in the cell. The electrode that has constant potential in one half-cell is called the reference electrode and the electrode in the other half-cell is known as the measuring or indicator electrode. The potential of a cell is equal to the potential of the reference electrode plus the potential of the indicator electrode plus the junction potential. The reference potential and the junction potential are constant, therefore the potential of the indicator electrode can be determined, and this can be related to the concentration of ions. This is described by the Nernst equation, which when simplified relates the cell potential to the concentration of ions. An electrode potential is also produced when varying concentrations of ions are separated by semipermeable membrane to the particular ion. Different indicator and reference electrodes are available. Reference electrodes are compared against the normal hydrogen electrode (NHE) with a potential of 0.00 V, and their relative potential is determined. One application of the potentiometric principle is the measurement of pH, i.e. the negative log of hydrogen ion concentration. Standardization of pH measurements has been reported by Wu et al.[29] Based on the principle of potentiometry, ISEs have also been developed.[30] These indicator electrodes at the tip have a thin glass membrane with a special composition that makes the electrode uniquely sensitive to the particular ion. The potential developed across the glass membrane (from the ions of the

analyte in the sample) is proportional to the concentration of the analyte. These indicator electrodes are now available for various elements such as sodium, potassium, calcium, ammonium and lithium. Indicator electrodes are also available to measure blood gases such as PO_2 and PCO_2. There are electrodes with tips composed of a silicone rubber matrix immobilized with a slightly soluble salt of the anion to be measured. These precipitate-impregnated membrane electrodes are developed to measure anions such as chlorides. On a similar principle, electrodes have been developed for bromine, cadmium, fluoride, etc. Besides being able to measure cations and anions by electrochemical means, certain nonion molecules are also being measured. Application of ISE is extended to measure such compounds, e.g glucose and blood urea nitrogen (BUN), using enzyme electrodes. Enzymes are impregnated in membranes that catalyze compounds to produce ions that are directly proportional to the analyte being determined. For example, enzyme urease is impregnated to act on urea from BUN. Urea is broken down to ammonium ions that are measured by a similar principle to that of the pH meter (change in hydrogen ion concentration). Besides potentiometric measurements, polarographic and amperometric measurements are also employed in electrochemistry. *Polarography* involves measurement of current flowing through an electrochemical cell and the potential between the two electrodes, when a constant electrical external voltage is applied to the cell. Application of ISE technology and Polarography are seen in Beckman ASTRA instruments. The Beckman ASTRA analyzer employs a polarographic electrode that responds to oxygen concentration. The rate of oxygen consumption as oxygen reacts with glucose, in the presence of enzyme glucose oxidase, is determined by the electrode. The rate of oxygen consumption is directly proportional to the glucose in the sample. The oxygen electrode is a polarographic electrode in that it measures a current limited by diffusion of oxygen through a Teflon membrane to the rhodium cathode, while the anode is held at a constant potential in reference to the cathode.

Amperometry involves measurement of current flowing through an electrochemical cell when a constant electrical potential is applied to the electrodes. Applications of amperometry are seen in the measurement of partial pressure of oxygen by the PO_2 electrode (Clark electrode). The oxygen that enters through a permeable membrane is reduced at the cathode. The current flow that results is directly proportional to the amount of oxygen. *Coulometry* is the measurement of coulombs or the amount of electricity flowing between the two electrodes in an electrochemical cell. The amount of electricity is directly proportional to the amount of substance produced or consumed by the oxidation/reduction reactions at the electrodes. Application of this technique has been seen in the Cotlove titrator for the measurement of chloride ions.[10]

4.10 Electrophoresis

A simple definition of electrophoresis is separation by electrical means. Charged particles are separated by electrical means. Although the term electrophoresis refers to separation of all charged particles, specific terms such as zone electrophoresis refer to separation of macromolecules such as proteins and lipoproteins for laboratory investigation. The macromolecules are separated using various supporting media such as cellulose acetate paper, polyacrylamide, agarose or starch gel. The choice of supporting media or matrix helps in the resolution of the separation. The equipment involves a power source to supply the electrical charge, a chamber to carry out the electrophoresis, and a densitometer to quantitate the separated molecules. The power supply is of two types, with either constant current or constant voltage. There may be advantages with the power supply with constant current, especially if the heat generated during electrophoresis increases, which causes the resistance to decrease, the voltage also decreases as seen by Ohm's law $V = I \times R$ (where V is voltage, I is current and R is resistance). Heat generated can affect the macromolecules by denaturing them. The resistance decreased due to heat may also affect the migration rate of the molecules. The power supply is connected to the electrophoretic chamber that contains the electrodes. The chamber is filled with the buffer, of appropriate pH and ionic concentration for conductance of electrical current. The level of buffer in the chamber is enough to cover the electrodes so as to complete the circuit after the supporting media with the sample applied is placed in the chamber. Parameters for current, voltage and time for electrophoresis are set according to the procedure and the procedure is completed. The separated molecules may be stained for proper identification of zones and quantitated using a densitometer. Densitometers are basically photometers with mechanisms for mounting the electrophoretic pattern that is made to move past a light beam on the opposite side of which is a detector. The recorder, if attached to the densitometer, converts the absorbances into 'peaks and valleys' or patterns which correspond to the density of the separated zones. Computerized systems are available that compute the results by converting the patterns into concentrations of the macromolecules present in the sample. With the advancing technology of microprocessors, the electrophoresis process has been automated by some manufacturers. Helena Laboratories has manufactured the REP system. This fully automated system performs electrophoresis from application of the sample to the

quantitation of results. Other leading manufacturers are Beckman and Ciba-Corning.

4.11 Capillary Electrophoresis

CE employs narrow bore (10–100 μm diameter) and 20–200 cm in length fused silica capillaries to separate, with greater efficiency, both large and small molecules for identification and studies. The high voltage (greater than 500 V) used in the technique generates electro-osmotic and electrophoretic flow of buffer solution and of ionic species in the capillary. This technique resembles a mix between PAGE and high-performance electrophoresis. Several advantages of this technique are noted: small sample volume; better resolution; easy automation and precise quantitation applicable to wider selection of analytes.

4.12 Isoelectric Focusing

In IEF, proteins are separated based not only on the charge they carry but also because they move through a medium that has a stable pH gradient. During the migration when the protein reaches a gradient that has pH equal to its isoelectric point, there is no net charge on the molecule. At this point the protein stops migrating and is separated out. The power source used in IEF is a high-voltage source, to enable the protein migration through the medium of high concentration of carrier ampholytes. Some modifications of this technique involve using various other media such as polyacrylamide gel that provides better resolution of proteins.

4.13 High-performance Liquid Chromatography

By definition chromatography is the separation of colored compounds. In the clinical laboratory, HPLC and GC have wider applications in toxicology and in therapeutic drug monitoring (TDM). HPLC is a type of LC, in which a mobile phase (liquid) is pressured to flow over a column (stationary phase). The mobile phase carries the sample through the column, during which components of the sample separate out based on their interaction with the stationary column packing. Each component is eluted out of the column and quantitated by the detection system. The components of HPLC are reservoir of solvent (mobile phase), pump, injection port, column, detector and readout device. The solvent reservoir is usually a bottle or a flask that contains the mobile phase. A solvent reservoir may be used if the pump is operated in the isocratic mode, or more than one reservoir used, if gradient mode is used in which the mobile-phase composition is changed over a period continuously by two or more solvents or in a stepwise fashion. The pump used is usually a reciprocating pump that provides a continuous flow of the solvent through the injector, over the stationary phase, the column and through the detection system. During the fill stroke the piston of the pump moves up the chamber. A certain volume of the mobile phase is drawn in the chamber through the inlet valve. In the pumping stroke, the inlet valve closes and the outlet valve opens and the piston moves down the chamber forcing the mobile phase or the solvent through the inlet port into the column. An aliquot of the sample is injected into the injection port with a microsyringe. Depending on the system, the sample may be held in a sample loop. In the inject mode the loop is rotated, causing the sample to be carried with the mobile phase into the column. A wide choice of columns is available. The column is usually made of stainless steel. There is a wide choice of packing materials. Silica is commonly used as a packing material. The detection system ranges from photometers, spectrophotometers and UV spectrophotometers to fluorometers and electrochemical systems. Various factors such as the composition of the mobile phase, the flow rate, the nature of packing material (stationary phase), the length of the column, etc. affect the resolution of components.

4.14 Gas Chromatography

Essentially the workings of a gas chromatograph are similar to a liquid chromatograph. In GC, the compound to be identified and quantitated is volatilized and carried by the mobile phase that is an inert carrier gas, through a column. In the column, constituents of the compound separate out and are identified or quantitated by a detection system similar to the one in LC. GC is of two major types: gas–solid chromatography (GSC) in which the packing material of the column is solid; and GLC where a nonvolatile liquid is coated on a solid column support.

The instrumentation involves the following:

- an oven with a temperature control;
- a chromatography column;
- inert gas, which is pressure regulated;
- a detection system and a recording system.

The prepared sample injected with a microsyringe through an injection port gets immediately volatilized due to the high temperature of the injection port and of the oven. The temperature of the oven is controlled so that constituents of the compound with the highest boiling point can be vaporized. The volatilized compound is carried by the inert gas through the column. The choice of inert gas depends on the detection system. Several detectors are available.[31,32] Nitrogen is usually used as the carrier gas with thermal conductivity and flame ionization detectors. Other gases used are argon,

helium and hydrogen. The columns may be made either of glass or stainless steel and are of various diameters and lengths. Usually 1/8 in. diameter columns are used. Capillary columns are about 0.8 mm in diameter and have no packing materials. The columns are of glass or fused silica. The inner walls of the columns act as the stationary phase. The narrower the diameter of the column the better the resolution of the constituents. Resolution of the constituents also depends on several other factors such as the nature of the packing material, the flow rate of the carrier gas and retention time. Diatomaceous earth is often used as packing material. Silica, alumina, and activated carbon are also used. The detectors in the clinical laboratories usually are thermal conductivity, flame ionization, or mass spectrometer type detectors. For details of theory and practice of chromatography refer to the textbook by Kaplan and Pesce.[33] For further reading refer to the book by Bender.[34]

4.15 Osmometry

Osmometry is the measurement of osmolality, that is the number of moles of particles of solute per kilogram of solvent. Osmolality is related to the osmotic pressure of the solution that regulates the movement of fluids between the cells and extracellular fluids. The instrument that measures osmolality is called an osmometer. Instruments that measure osmolality can theoretically be built on any of the colligative properties of solutions, which are increase in osmotic pressure, increase in boiling point, lowering of vapor pressure, and decrease in freezing point. The decrease in freezing point property has commonly been used to measure the osmolality of a solution as it is more practical. This property is based on the fact that the freezing point of water is lowered by 1.86 °C per molal of particle. The instrument involves an insulated coolant bath that holds an antifreeze solution such as ethylene glycol at −6 °C by a refrigeration unit. The sample (about 1 mL) such as serum or urine is placed in a small glass tube. The tube is placed in the instrument such that the stirrer and a thermistor dip in the sample. The thermistor is attached through a galvanometer to a read-out device. When the tube holding the sample is lowered into the coolant, the temperature of the sample starts to fall below the freezing point until it is a few degrees below the freezing point. At this point, the stirrer starts to vigorously stir the sample raising the temperature of the sample so that the sample forms a slush when the freezing point temperature is reached. The difference between 0 °C and the temperature when the slush is formed is the depression of the freezing point by the particle of the solute. This difference in temperature is related through the galvanometer to a read-out device that gives the reading in osmol kg^{-1}.

4.16 Solid Scintillation Counters

Solid scintillation counters (γ-ray counters) are instruments that are employed in the measurement of nuclear radiation. Nuclear radiation is emitted by an isotope of an atom when the ratio of neutrons to protons in its nucleus is unstable. In the process of stabilization of the nucleus the atom emits energy in the form of radiation. The isotope commonly employed in the clinical chemistry laboratory is iodine-125 and at times cobalt-57. Iodine-125 is in an excited state due to its unstable nucleus. A γ-ray is emitted when iodine-125 reverts to its ground state. Scintillation counters measure the γ-rays emitted by iodine-125 or cobalt-57.

Scintillation counters comprise of a crystal (sodium iodide–thallium) that is encased in a thin aluminum foil. This crystal, also known as phosphor, is flushed to a photomultiplier tube. Other components of the scintillation counter include a discriminator or a pulse height analyzer and a scaler. Processed samples that contain iodine-125 when placed in the well of the scintillation counter, either manually or by automation, emit γ-rays. The γ-rays strike the crystal that produces a flash (scintillation). This radiant energy is captured by the photomultiplier tube. The photomultiplier tube converts the light energy into electrical energy that may be amplified in proportion by an amplifier. The pulse height analyzer or the discriminator allows only energy of certain magnitude of the isotope to be measured; it sorts out pulses of certain heights. All voltage pulses below or above a certain magnitude are eliminated from reaching the scaler and thus from counting. Pulses are counted as counts per minute by the scaler.

5 ADVANTAGES AND/OR LIMITATIONS OF INSTRUMENTS AND/OR METHODOLOGIES

Numerous techniques, methods and instruments are available for the determination of an analyte. Therefore the decision on the choice of method, technique or instrumentation plays a critical role in the quality of the results. Sensitivity and specificity are two important criteria in the quantitation of an analyte. Sensitivity refers to the smallest concentration of an analyte that can be determined by a particular methodology or an instrument. Specificity refers to a particular analyte in question. Both sensitivity and specificity should not be compromised, and other factors such as turnaround time for the results of analysis and cost per analysis play an important role. Most methodologies, techniques, and instrumentation have certain advantages and limitations. The objective therefore in choice of instrumentation or methodology

is to utilize one with minimum limitations and optimum advantages.

Much of the chemical analysis in a clinical diagnostic laboratory is performed by spectral methods. In fact "spectrophotometry is the corner stone of analytical instrumentation".[35] With rapid advances in spectrophotometer designs, including truly monochromatic light beams by means of tunable lasers, fiber optics, ultra fast scanning spectrophotometers and extremely sensitive photodiodes, resolution has improved tremendously.[35] However, due to high sensitivity and accuracy there is a great need for performance checks and quality control.

Fluorimetric measurements have provided increased analytical sensitivity along with specificity. A major advantage of fluorimetry is that it is 100 to 1000 times more sensitive than absorption measurements. Much progress has been made in the development of instruments and methods.[36] Time-resolved fluorimeters have eliminated background interference and, by averaging signals, have improved precision. Detection limits of approximately $10-13\,\mathrm{mol\,L^{-1}}$ can be achieved. Fluorimetric measurements have their limitations. Fluorescence is affected by many variables such as pH, temperature, presence of quenching compounds and intensity of incident light.

In AA spectrophotometry, the two instrumental performance characteristics are sensitivity and detection limits. Sensitivity is a convention for defining the slope of absorbance versus concentration calibration for each element. For a flame AA it is expressed as the concentration of an element in micrograms per milliliter that will produce an absorbance of 1% absorption. In absorption, unit sensitivity is the micrograms of element per milliliter that will give an absorbance of 0.0044. For a graphite system, sensitivity is stated in terms of weight in picagrams of element that will produce 1% absorption. The detection limit is the lowest concentration that can be measured from the baseline noise. For a flame system it is the concentration that will produce a signal-to-noise ratio of 2 to 1. For a graphite system it is expressed in terms of weight of an element that will produce the same ratio.[28]

In the measurements of electrolytes by potentiometric methods, the results are reported not as activity of ions but activity multiplied by a certain factor. In this case the results reported by flame photometry and by potentiometric methods are not significantly different from each other in normal samples. However, major differences between the two methodologies can occur in certain pathological conditions when the mass water concentration in the sample is abnormal, and also for severe hyperlipemia or high protein concentrations.

6 CALIBRATION/STANDARDIZATION OF INSTRUMENTS

Calibration and standardization of clinical laboratory instruments are essential for validity of results. Calibration involves adjustment or manipulation of a component or components for correct output of the results. Standardization refers to analyzing a pure substance of a known concentration or a series of concentrations that can provide a calibration curve, against which an analyte of unknown concentration will later be compared. In practice, a standard may be analyzed, and as the recorder displays the results, the component of the instrument can be calibrated so that the recorder displays the exact concentration of the standard. In spectrophotometry, and other instrumentation, where absorbance of the unknown is compared with the absorbance of the standard for calculations of the results, minor errors in calibration of wavelength or other parameters are compensated since the unknown sample is being compared with a standard of known concentration. Using a series of standards over a wide range of concentrations, rather than a single standard, in addition provides a measure of photolinearity and agreement with Beer's law. However, when calculations of the results are based on certain constant values such as molar absorptivities or absorption coefficients then calibration of the instrument should be conducted with utmost care. In spectrophotometry, wavelength calibration is performed by use of solid filters such as holmium oxide or didymium. In verifying the band width of a spectrophotometer, the range of wavelength at one-half the peak transmission is taken into consideration. All spectral instruments are adjusted for baseline correction, either with a water blank or a reagent blank. In electrochemical methods, reference electrodes are calibrated against the hydrogen electrode. Measuring electrodes are calibrated against two different concentrations of standards to provide a calibration curve. The slope of the curve, along with the intercept, is then used by microprocessor to calculate the concentrations of the samples. In chromatography, standards are injected as pure analyte and, from the standard curve, the peak area of the unknown is compared with the standard to determine the unknown concentration.

7 AUTOMATION IN CLINICAL CHEMISTRY LABORATORY

Automation in the clinical chemistry laboratory began with the introduction of continuous flow single channel autoanalyzers by Technicon Corp. Skeggs introduced this system in the 1950s. These analyzers were called continuous flow because they employed peristaltic pumps and

plastic tubing to advance the samples and the reagents. Air bubbles separated the specimens and also cleaned the inner tube walls to minimize carry over of specimens. The incubation system included a mineral oil bath with a glass coil through which sample mixed with reagents advanced at a slow speed that allowed for incubation and color formation. The color formed during incubation was measured by a flow cell after air was debubbled. This system went through several modifications; SMAC (Sequential Multiple Analyzer Computerized) and CHEM 1+ were the modified versions. As in single channel autoanalyzers, automation mimics the steps of routine analysis, such as aspiration of the sample, addition and mixing of reagents, incubation of sample and reagent and measurement of color formation. It minimizes or even replaces human involvement in the process. Specimen identification and analysis of specimens are aided by bar codes. Autoanalyzers are classified based on their mode of operation. Continuous flow analyzers process samples sequentially, and each in the same manner. Each sample gets analyzed for all the tests available. Continuous flow analyzers have an advantage in a high-volume laboratory. The disadvantages of this system are that reagents are wasted if all the tests available are not requested. An example of continuous flow analyzer is the CHEM 1+ analyzer by Technicon. Batch analyzers as the term indicates analyze specimens sequentially in a run for a particular test at a time. Specimen analysis is performed from a carousel in discrete or individual cells or cuvettes. An example of batch analysis is COBAS-BIO that works on the principle of centrifugal analysis. Random access analyzers allow analysis of specimens in any order at any time. Tests may be performed as profiles or individually. Random access analyzers are selective and discrete. Discrete analysis allows each specimen to be analyzed in its own separate space. The main advantage of these analyzers is that they save reagents, facilitate Statin analysis and prevent any carry over of samples. Random access analyzers are very popular. Today's random access analyzers make the analytical process more integrated and efficient. These analyzers are built to increase productivity. Beckman's Synchron LX Clinical Systems, developed for a high-volume laboratory, offer random access, Statin and batch profiling of more than 80 analytes, including critical care tests, general chemistries, TDM, and drugs of abuse, thyroids and other esoterics (DATs). System operation is so automated that it requires an absolute minimum of a human interface performing up to 2880 tests per hour. Beckman's Synchron CX 9 ALX is also a random access analyzer, and offers a wide menu for analysis from general chemistry and urine chemistries to TDM and DATs. The random access analyzers provide access for a selectable number of tests. Reagents are available in a variety of ways: a pack in an automated clinical analyzer has a binary code; Paramax 720Z has different tablets; or reagent impregnated slides such as in VITROS. A wide choice of autoanalyzers is available from high volume to desktop. All of these analyzers now are interfaced and integrated with computers that control the process and handle the data. Standards for transmission of information between clinical instruments and Laboratory Information Systems have been developed.[37,38]

8 QUALITY CONTROL AND QUALITY ASSURANCE

Quality control and quality assurance refers to total quality management of the clinical laboratory. It refers to analyzing the overall performance of the laboratory in terms of laboratory results, consumer satisfaction (physicians and nurses), patient satisfaction, and laboratory staff satisfaction. Quality control implies a more limited aspect of the overall quality management. It refers to technical aspects, such as the methodology and the quality of laboratory data output based on statistical applications. US clinical laboratory regulations[39] require quality control procedures to be set for each clinical laboratory. Quality assurance implies a broader term guaranteeing overall quality of the laboratory performance. Quality control involves pre-analytical, analytical and post-analytical controls. Pre-analytical controls include such things as proper identification, collection and processing of patient samples. Analytical controls include selection and execution of methodologies, incubation temperature checks, calibrators, calibration/standardization of instruments and reference controls used in the procedures. Post-analytical checks are based on statistics and quality control charts. Selection of the correct methodology with accuracy and precision in its execution plays a very crucial role in quality control. Methods may be subject to random or systematic errors. Barnett and Youden[40] in 1970 first introduced a scheme for selecting and evaluating clinical laboratory methods. General discussion of the philosophy of method evaluation in relation to the overall quality assurance process has been developed by the International Federation of Clinical Chemistry (IFCC). Several articles on the topic of method evaluation have been published in the *Archives of Pathology and Laboratory Medicine* in 1992.[41] A textbook on the selection of methods has also been published.[40] Accuracy in a procedure is defined by IFCC as the closeness of the agreement between the measured value of an analyte and its true value. The true value is determined by using reference methods. Precision of a method refers to obtaining the same laboratory value on replicate determinations. When reference controls are

run, along with the patient specimens, using selected methodology, reference values are obtained. When these obtained reference values are compared against the range of values provided with the reference controls for that particular analyte, and if the values fall within the expected range, this attests to the validity of the methodology employed. A common method is to plot the obtained reference values on a chart each day against the day the values were determined. This chart has a mean known value for the analyte, with the upper and lower limits (range) set at certain standard deviations from the mean. When the obtained reference values fall within the range of standard deviation set, the ''run'' is said to be ''in control''. Such control charts are called Levey–Jennings charts. The interpretation of the control data in the laboratories is by implementing Westgard Multirule Chart. Several books and publications by Westgard are available in the area of Total Quality Management for additional reading.[42]

9 FUTURE DEVELOPMENTS OF INSTRUMENTS

At the December 1998 American Association for Clinical Chemistry meeting entitled Preparing for the Millennium: Laboratory Medicine in the 21st Century, topics such as what technologies will emerge? dominate? and other topics relating to the future of the clinical laboratory were discussed. From this and other information, it is evident that robotics will play a very important role in the future development of medium to high volume instruments. Interface and communication standards will be needed for controlling laboratory instruments by remote interface. There will be a trend towards modular automation, and automation will be guided by highly sophisticated software in the forms of CD ROM. Workstations to monitor and control several different clusters of autoanalyzers by a single operator will be available that will reduce the cost. The configuration of various workstations is described by Boyd et al.[43] Many of the autoanalyzers with bidirectional interfaces will be monitored, and controlled by the mainframe computer. Rapid growth in point of care testing (POCT), will demand smaller, operator friendly, and more easily portable instruments that employ dry chemistries or reagent cartridges. With rapid advances in microprocessor technology and miniaturization of electrodes, instruments employing electrochemical methods and maintenance-free electrodes will find greater applications in POCT. Hand-held analyzers, that utilize whole blood for glucose and cholesterol testing will be commonly used in POCT and in the home healthcare industry.

ACKNOWLEDGMENTS

I would like to thank Adam Holyoake, Jenny Cossham and the rest of the staff at John Wiley & Sons for giving me this opportunity and helping me to prepare this manuscript. My sincere thanks go also to Dr Robert Meyers, editor-in-chief and the rest of the editorial staff for their comments and suggestions.

My thanks also to Albert Akiyama of Beckman Coulter for directing me to the website of Beckman Coulter and providing me with some literature and brochures about the company's clinical analyzers. I also appreciate the efforts of Dr Ralph Ito of Olympus America in helping me to obtain information about the company's analyzers.

Last but not the least I would like to thank my wife Smita Karnik for typing and formatting the manuscript.

Lipid analyses are primarily used for determining the risk of diseases resulting from atherosclerosis, including coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral arterial disease. These disorders are often marked by hyperlipidemia, with increased serum low-density lipoprotein cholesterol (LDL-C) and apolipoprotein (Apo) B, but decreased high-density lipoprotein cholesterol (HDL-C) and Apo A-I. For use in risk assessment, serum cholesterol, LDL-C and HDL-C cut-points have been derived from epidemiological data from several nations. The acceptance of these cut-points, coupled with the remarkable heterogeneity of lipoproteins, has made standardization of cholesterol analytical procedures essential. An international network of laboratories (the Cholesterol Reference Method Laboratory Network (CRMLN)) coordinated by the US Centers for Disease Control (CDC) was formed to address this issue. Thus, several reference methods have been adopted and are used to standardize and certify the commercial reagents for lipid assays for use in the routine clinical laboratory. Other standardization efforts include those by the International Federation of Clinical Chemistry, World Health Organization (WHO) and CDC on Apos or lipoprotein(a) (Lp(a)). In addition to analytical standardization, it is important to standardize preanalytical procedures, and to be aware of potential biological variability.

In the 1980s and 1990s, significant advances have been made in the procedures for routine analysis of lipids and lipoproteins. The analyses have become much more precise and efficient, frequently performed in automated analyzers using small sample volumes. A variety of enzymatic methods for cholesterol and triglyceride (TG) measurements are in current use. HDL-C is generally determined after precipitation of low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL). LDL-C is calculated from the difference between total cholesterol (TC), and the sum of HDL-C and a total TG-derived estimate of the very low-density lipoprotein cholesterol (VLDL-C) (the Friedewald equation). Several direct methods for measurement of LDL-C and HDL-C have been introduced with improvement in performance and labor efficiency, Apo B which is associated with LDL in equimolar ratio and Apo A-I which is associated with high-density lipoprotein (HDL) may be measured in conjunction with LDL-C and HDL-C or used in their place for clinical assessment. Other important lipid measurements include the C and E Apos, Lp(a), TG-rich remnant lipoproteins, lipoprotein particle size and markers of oxidative stress.

1 INTRODUCTION

Several of the many lipids found in humans have been identified as biomarkers of clinical conditions. By far the most important of these conditions is CHD, which is the number one cause of death in most first-world nations. In 1984, the Lipids Research Clinics Coronary Primary Prevention Trial provided definitive evidence that lowering serum cholesterol reduces the risk of contracting coronary artery disease.[1,2] In the United States, the US Public Health Service responded to these findings. Thus, the National Cholesterol Education Program (NCEP), a cardiovascular risk factor education program administered by the Office of Prevention, Education, and Control at the National Heart Lung and Blood Institute of the National Institutes of Health (NHLBI), was established the following year.

The coordinating committee of the NCEP now directs expert panels and working groups to develop lipid diagnostic and treatment guidelines. These panels include the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (The Adult Treatment Panel), the Expert Panel on Population Strategies for Blood Cholesterol Reduction (The Population Panel), the Expert Panel on Blood Cholesterol Levels in Children and Adolescents, the Laboratory Standardization Panel, and the Working Group on Lipoprotein Measurement. Reports of the NCEP Panels and Working Group are available from the United States Public Health Service National Institutes of Health (NIH) or on the NHLBI web site (www.nhlbi.nih.gov).

In 1993, the second report of the Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults was released, taking precedence over the first (1988) report by the panel. It, like the first report of the panel, continued to consider LDL (specifically LDL-C) to be the primary target of lipid lowering therapy (see Table 1).[3,4] However, it drew additional attention to HDL-C as a "negative" risk factor for CHD risk, and recommended that it be part of initial cholesterol testing. Diagnostic and treatment recommendations were provided for the primary prevention of CHD in adults without evidence of disease, and secondary prevention for patients with established CHD. These include epidemiologically based cut-points for cholesterol for use in diagnosis and treatment.

The challenge facing a campaign to institute universal treatment cut-points is that all laboratories performing the analysis must be standardized to the same accuracy base. This is different from traditional laboratory medicine where different testing methods often yield results that are numerically different. Under these circumstances, a reference range is developed by each institution or for each method. On the other hand, when the same treatment cut-points are universally applied, the same accuracy base for testing, the same sample types (serum, plasma or whole blood) and specimen collection conditions (posture, fasting status, and so forth) must be carefully maintained.

In 1995, the Working Group on Lipoprotein Measurement established the current analytical goals for measurement of lipid markers in the screening and monitoring of hyperlipidemias (Table 2). In addition, the limits for routine methods were formalized, guidelines for specimen collection, types and storage provided, and the need to obtain serial measurements on each patient was stressed. Reference methods recommendations were also made, along with recommendations to continue to link routinely used methods with epidemiological data obtained using the same methods.[5–8]

Naturally, the art and science of lipid testing run in advance of its standardization, so the standardization of many newer tests has not yet been addressed. This may be because of a lack of reference materials, reference methods or epidemiologically derived treatment cut-points. The evolution of lipid testing nearly always far precedes the recognition of how such parameters as biological matrix affect analyte behavior. Once these effects are known, how to assimilate this knowledge into

Table 1 NCEP Adult Treatment Panel II categories for total and LDL-C concentrations for patients with and without CHD

TC category	TC mg dL^{-1} (mmol L^{-1})	LDL-C category	LDL-C mg dL^{-1} (mmol L^{-1})
Patients without CHD			
Desirable	<200 (5.2)	Desirable	<130 (3.4)
Borderline-high	200–<240 (5.2–6.2)	Borderline	130–<160 (3.6–4.1)
High	≥240 (6.2)	High-risk	≥160 (4.1)
Patients with CHD			
		Optimal	≤100 (2.6)
		Higher than optimal	>100 (2.6)

Table 2 NCEP performance criteria for lipid and lipoprotein measurements

Analyte	Bias	Imprecision	Total error (%)
TC	≤3% of RV	CV ≤ 3%	≤9
TG	≤5% of RV	CV ≤ 5%	≤15
HDL-C	≤5% of RV	SD ≤ 1.7 at <42 mg dL^{-1}	≤13
		CV ≤ 4% at ≥42 mg dL^{-1}	
LDL-C	≤4% of RV	CV ≤ 4%	≤12

CV, coefficients of variation; RV, reference value determined by CDC reference methods; SD, standard deviation.

the development of assay standards and calibrators must be researched.

The standardization of lipids and lipoproteins presents a particular challenge because of their heterogeneous nature. To enable laboratories and manufacturers of lipid reagents to achieve the analytical goals set by the NCEP, the CDC created the CRMLN.[9,10] Using reference methods and fresh serum samples, analytical accuracy is passed from this laboratory network to the ''field''. CRMLN has an international presence, currently with six North American (five US, one Canadian), three European (United Kingdom, The Netherlands and Italy) and one Asian (Japan) laboratories. Each of these laboratories has instigated or participated in standardization efforts in their respective countries. Other programs include the National Initiative on Cholesterol Accuracy, Methods and Standardization (NICAMS) in the United Kingdom, the cholesterol target assignment of the External Quality Assessment Scheme (EQAS) control and calibrator materials conducted by the Rotterdam University Hospital Network Laboratory in The Netherlands, the Programa de Evaluacion Externa de Calidad in Argentina, as well as several lipid proficiency surveys using fresh or frozen human sera that are traceable to a reference method accuracy base.

As discussed, the NCEP has focused on standardization of lipoprotein cholesterol measurements. Advances in standardization of lipid methods that are outside the scope of the NCEP program are being addressed by other organizations. For example, the International Federation for Clinical Chemistry (IFCC), the WHO and the CDC are collaborating on Apo and Lp(a) standardization efforts to derive international reference materials.[11–13]

It should be stressed that in addition to being important risk factors for CHD, lipid markers are useful in the diagnosis and monitoring of several other disease states. These include primary and secondary hyperlipoproteinemia associated with obesity, disturbed glucose tolerance, diabetes mellitus, diseases of the kidney, liver, thyroid, pancreas, and gastrointestinal track, cancer, and perhaps neurodegenerative diseases.

2 LIPOPROTEIN STRUCTURE AND BASIC BIOCHEMISTRY

2.1 Classification

Lipids are a diverse class of compounds. Many have in common only their uniform solubility in organic solvents like ethers, carbon disulfide and carbon tetrachloride. Of this diverse class of compounds, only a few have been found to be of use in the study or diagnosis of important clinical conditions. The primary clinically significant lipids are members of the most abundant categories, including triacylglycerols (usually referred to as TGs by clinicians), and sterol compounds. TGs and the primary sterol, cholesterol and its esters, are associated in blood in lipoprotein particles. These particles contain lipid, as well as several proteins that facilitate the transport and tissue distribution of the hydrophobic lipids within the primarily aqueous environment of the blood and lymph.

2.2 Structure

2.2.1 Triacylglycerols (Triglycerides)

The simplest description of a TG is the esterification product of glycerol and three fatty acids. These neutral lipids are biosynthetic products of L-glycerol and fatty acids. The specificity of glycerol kinase in the first step in the synthesis of acylglycerols maintains the stereointegrity of TGs, which may contain three identical fatty acid esters (a simple TG) or contain a mixture of fatty acids (a mixed TG). Generally, mono- and diacylglycerols are present only as partial breakdown products of triacylglycerols.

Since mixed fatty acids are common, it is necessary to differentiate the three positions on the glycerol backbone. The three positions are designated 1, 2 and 3, or α, β and α'. A TG with two different fatty acids can exhibit up to six distinct molecular structures. Although the TGs are structurally diverse, the possible structures are limited both by species-specific dietary intake and enzymatic specificity.

Human triacylglycerols primarily contain 16- (C_{16}) and 18-carbon (C_{18}) fatty acids with smaller amounts of shorter (usually C_{12} or C_{14}) or longer fatty acids (commonly C_{20} or occasionally C_{22}). The fatty acids may have from one to several double bonds with the first double bond often occurring between the C_9 and C_{10} positions. Certain $w3$ and $w6$ fatty acids (fatty acids with the double bond closest to alkyl end are designated by an w or n) are required for normal growth and

development. These include α-linolenic acid ($C_{18}:3w3$), docosahexanoic acid ($22:6w3$), linoleic acid ($18:2w6$), and arachidonic acid ($20:4w6$). Some fatty acids from the $w3$ and some from the $w6$ series are required for normal skin, growth, vision, learning, reproduction, liver function and hydration.

The unsaturated fatty acids have a nonlinear carbon sequence. This means the van der Waals forces that cause attraction between the aliphatic tails of saturated fatty acids are weaker for unsaturated fatty acids. Hence, unsaturated fats have a lower melting point than saturated fats of the same chain length.

Usually the double bonds of fatty acids are found in the *cis* conformation, but *trans* fatty acids are present in TGs that have undergone industrial hydrogenation for use in the manufacture of margarine and shortening. They are also present in a portion of the fatty acids in fats of ruminant mammals (produced by bacterial action within the rumen).

Fatty acids with multiple double bonds (polyunsaturates) may be classified on the basis of the first double bond from the aliphatic end of the molecule. Those with the first double bond between the 3rd and 4th carbons are called *n*-3 (or *w*-3) fatty acids. Another common class of unsaturated fatty acids is the *n*-6 (or *w*-6). One (monounsaturated) to five double bonds occur most often.

2.2.2 *Cholesterol and Cholesterol Esters*

Cholesterol **(1)** is a derivative of the fused, reduced polycyclic structure perhydrocyclopentanophenanthrene **(2)**. For cholesterol, two methyl groups (C_{18} and C_{19}), a hydroxy group (at C_3), an eight carbon branched aliphatic chain (at C_{17}), and a double bond (at C_5-C_6) are added to this basic structure. Unlike triacylglycerols, cholesterol is not saponifiable. However, cholesteryl esters, containing unsaturated fatty acids, are synthesized in, for example, HDL particles. This occurs as the result of the action of lecithin–cholesterol acyltransferase (LCAT) that is present in HDL. LCAT converts the so-called free cholesterol present at extravascular sites to esterified cholesterol for "reverse-cholesterol transport" by transfer of the fatty acid at the β position of lecithin (phosphatidylcholine) to the C_3 hydroxy site of cholesterol. Thus, a concentration gradient is set-up that encourages further diffusion of cholesterol from the extravascular space.

(1)

(2)

2.2.3 *Basic Lipoprotein Structure*

Lipoproteins and the closely related chylomicrons are assemblages of proteins, called Apos, with TGs, cholesterol, cholesterol esters, phospholipids, and other compounds (see Figure 1). Free cholesterol, the hydrophobic heads of phospholipids, and the hydrophobic portions of Apos occupy the monolayer at the lipoprotein surface. The core of the particle contains cholesteryl esters and TGs. The resulting aggregates vary in size, density and function.

The largest of the particles are chylomicrons and VLDLs. These contain large amounts of TGs and considerable cholesterol that are destined for transport from the intestine and liver, respectively. The TGs in these particles are hydrolyzed primarily at the capillary surface of adipose and muscle tissue by the enzyme lipoprotein lipase. The resulting fatty acids are transported into the cell. This decreases the size of the particles and increases their density, as the fraction of Apo, cholesterol and cholesteryl esters that are present increases. A fraction of VLDL is successively converted by this process into intermediate density lipoproteins (IDLs) and LDLs, whereas a equal or larger portion are converted to remnant particles.[14] Likewise, chylomicrons are converted to chylomicron remnants. Both of these remnants are called TG-rich lipoprotein remnants. The remnants of VLDL and chylomicrons, and LDL particles are atherogenic, and are relatively slowly removed from the circulation by binding to hepatic receptors.

2.2.4 *Lipoprotein(a)*

Lp(a) is an atherogenic lipoprotein particle whose function is not currently clear. Structurally, Lp(a) is an LDL particle with its single copy of Apo B-100, plus one copy of a protein designated Apo(a) that is covalently linked by a disulfide bond to the Apo B-100. Apo(a) is a glycoprotein with a variable number of peptide subunits that have a high degree of homology to the highly conserved kringle subunits of plasminogen, the central protein in the fibrinolytic system. Variability in the number of kringle repeats occurs from person to person, and is responsible for Lp(a) sizes ranging from 187 to 662 kD.

2.3 Classical Techniques for Separation of Lipoproteins

2.3.1 *Ultracentrifugation*

Historically, lipoproteins have been separated by methods based on their different physical properties. While ultracentrifugation is now rarely done for clinical purposes, it is the method that gives us much of the current lipoprotein nomenclature and it is still widely used in research.

Figure 1 A simplified overview of lipoprotein characteristics. The various particles are represented by double rings to indicate that each is made up of an outer layer that contains phospholipid, free cholesterol, and Apos (A-I, B-48, A-IV, E, C-I, C-II, C-III, B-100, A-II). The inner ring represents the particle core, which contains TGs and cholesterol esters in varying proportions. The density (*d*) and electrophoretic mobility of the various particles are indicated at the bottom of the figure. Each lipoprotein illustration represents a family of particles with a distribution of different sizes and densities.

The principal method for isolation of lipoproteins is the sequential flotation technique.[15] In this method, the density of the plasma is adjusted to upper limit of the class of lipoprotein particle to be isolated (see Table 3) before centrifugation. The lipoprotein floats at a specific density and can be removed from the solution. Thus, after removal of the chylomicron by a short centrifugation, and a longer one for removal of VLDL, the density of the plasma can be adjusted to 1.019, 1.063 and 1.210 with 18-h centrifugation between adjustments. The density of salt solutions prepared from NaCl, KBr or NaBr can be determined from the refractive index of the solution or from a density meter, a glass tubing shaped like a tuning fork that produces pitches that are dependent on the density of the solution with which it is filled.[16]

Distinct classes of VLDL, IDL, LDL can be isolated by using density gradient ultracentrifugation,[17] or rate zonal ultracentrifugation.[18] These techniques have been refined, allowing the separation of three to seven LDL subfractions.[19,20] In addition, several HDL subfractions may be isolated.

Flotation ultracentrifugation to remove chylomicrons and VLDL can be combined with precipitation of LDL from the LDL–HDL mixture, and chemical or enzymatic assay of cholesterol to determine the cholesterol in each

Table 3 Physical properties of lipoprotein classes

Lipoprotein class	Particle density ($g\,mL^{-1}$)	Molecular wt ($\times 10^{-6}$ Da)	Diameter (Å)	Electrophoretic mobility
Chylomicron	<0.94	50–1000	750–12 000	Origin
VLDL	0.94–1.006	10–80	300–800	Prebeta
IDL	1.006–1.019	5–10	290–350	Slow prebeta/beta
LDL	1.019–1.063	2–3	230–290	Beta
HDL	1.063–1.210	0.07–0.40	50–120	Alpha
Lp(a)	1.05–1.08	1.9–6.6		Fast prebeta

of the lipoprotein fractions, in a technique that is called β-quantification (see below).[21]

2.3.2 *Electrophoresis*

As indicated in Table 3, lipoprotein particles can be separated by electrophoresis. Historically, this led to the classification of six different hyperlipoproteinemic phenotypes: type I, type II-a, type II-b, type III, type IV and type V (see review by Schaefer and Levy[22]). This classification system results in large part from the relative amounts of lipoproteins present in each of four distinct lipid-staining bands. The relative migration of the lipoproteins compared to plasma proteins is in the so-called α- and β-regions (Table 3). These are strictly qualitative classifications, and as cholesterol quantification became a routine procedure, electrophoretic systems came to be used only in classification of rare hyperlipoproteinemias. However, advances in automation, scanning, and enzymatic lipid staining have led to commercial development of automated instruments that electrophorese specimens on agarose, stain the gel, scan the electrophoretograms and calculate the specimen lipoprotein fraction cholesterol concentration.[23,65]

2.3.3 *Chromatography*

Lipoproteins can be separated by chromatography using size discrimination as the criterion. Gel permeation (size exclusion) high-performance liquid chromatography (HPLC)[24] or fast-performance liquid chromatography (FPLC)[25] columns can be used to separate the primary lipoprotein classes and subclasses of VLDL, LDL, and HDL. A commercially available system has been placed on the market that is dedicated to the separation of lipoproteins and set up to allow on-line enzymatic measurement of cholesterol in each fraction. Automated assays that correlate well with those obtained by sequential ultracentrifugation are available.[26]

3 IMPORTANT CLINICAL CONDITIONS

NCEP guidelines indicate that serum cholesterol levels $\geq 200\,mg\,dL^{-1}$ ($5.2\,mmol\,L^{-1}$) are associated with increased risk of CHD.[3,4] In point of fact, serum cholesterol levels between $150\,mg\,dL^{-1}$ ($3.88\,mmol\,L^{-1}$) and $200\,mg\,dL^{-1}$ ($5.2\,mmol\,L^{-1}$) are associated with a graded increase in CHD risk, especially when other risk factors are present.[27,28] These other risk factors include, but are not limited to, genetics, age, gender, smoking history, blood pressure, and serum TGs, Lp(a), homocysteine, LDL-C and HDL-C.[28,29]

Over 95% of individuals with hyperlipidemia (dyslipidemia), elevated blood lipid concentration, suffer from hyperlipoproteinemia, elevated serum lipoprotein concentration. As already discussed, LDL-C is a primary focus of the NCEP guidelines and is a better risk marker than TC, and HDL-C is a negative risk marker. On the other hand, the ratio of TC or LDL-C to HDL-C may even more faithfully predict risk.[30] The importance of detection of hypertriglyceridemia for risk assessment is not as clear as that of hypercholesterolemia, but evidence from cellular, genetic, and molecular, as well as epidemiological and clinical studies, suggests that it is associated with increased risk.[31]

Hypocholesterolemia is relatively frequent in individuals with affective disorders (depression, bipolar disorder, and schizoaffective disorder).[32] Low cholesterol levels are also associated with some forms of cancer,[33,34] but this may be an effect of the disease rather than a cause.[35] Extremely low concentration is a prognostic indicator of patient survival in hospitalized patients,[36] and is associated with protein–calorie malnutrition.[37] Low levels of cholesterol are prevalent in human immunodeficiency virus-1 (HIV-1) infection even before progression to acquired immune deficiency syndrome (AIDS), and marked hypocholesterolemia, as a sequel to malabsorption, is associated with poor prognosis in AIDS patients.[38] Chronic hypotriglyceridemia is not generally a diagnostic or prognostic marker. However, like hypocholesterolemia, it is associated with malabsorption syndromes. For example, AIDS patients with fat malabsorption, and chronic diarrhea and weight loss are thus affected.[39]

Some individuals with total serum cholesterol concentrations that are deemed low risk by the NCEP develop CHD, just as some people with serum cholesterol concentrations associated with markedly increased risk do not. To begin with, this occurs because the cholesterol associated with the various lipoproteins that comprise total serum cholesterol may be either positively or inversely linked to the development of atherosclerosis, the underlying cause of CHD. Furthermore, the atherosclerotic lesion initiation and development are multifactorial processes. There seem to be several factors that are agents in or influencers on the development of atherosclerosis. These include low-grade coagulation,[40] inflammatory processes,[40,41] increased oxidative stress or reduced antioxidant levels,[41] and factors contributing to one or more of these conditions, such as excess plasma homocysteine.[42]

Obesity is associated with changes in serum lipid concentrations that are associated with increased risk of CHD. This is apparently in large part the result of insulin resistance, an eventual consequence of excess adiposity, especially in the abdominal region.[43] Insulin resistance is

associated with decreased adipose and muscular uptake of glucose and fatty acids because of downregulation of insulin receptors on the cellular membrane. These processes lead to increases in serum TG levels, decreased HDL-C, and changes in the composition of LDL-C. Overproduction of TG-rich VLDL, fewer HDL particles, and more small dense LDL particles occur.[44]

Insulin resistance leads to type II diabetes when insulin production is less than that needed to maintain cellular glucose uptake. Besides obesity, type II diabetes and hyperlipidemia, hypertension occurs as a consequence of persistent insulin resistance. This constellation of clinical outcomes, sometimes called syndrome X,[45] is associated with extremely high risk for the development of atherosclerosis and CHD.

Early dietary studies suggested that fat and total calorific intake is related to the risk of colon, prostate and breast cancer (see Wu et al.[46]). However, except for low levels of HDL cholesterol, serum lipids do not correlate with the cancer incidence.[47] It appears that some other factors associated with increased fat intake, e.g. obesity or red meat consumption, and not dietary fat intake or serum lipids alone correlate with the risk of cancer.[46]

4 LIPID AND LIPOPROTEIN METHODS

4.1 Overview

Procedures for measurement of clinically important lipids have evolved over the last half of the twentieth century. Some of the earliest techniques for measurement of serum lipids are still in use as reference methods. In the clinical laboratory, lipids are usually measured by quantification of colorimetric products of enzymatic reactions. Apos are assayed by a variety of immunoassay techniques. Table 4 summarizes methods for assay of the lipid components of lipoproteins.

Table 4 Methods for analysis of the lipid components of lipoproteins

Method type	Principle	Refs.
	Cholesterol	
Definitive	Isotope dilution/mass spectrometry (NIST)	48–50
Reference	Abell–Kendall (CDC)	51, 52
Routine	Enzymic (esterase, oxidase, peroxidase)	53–56
	HDL Cholesterol	
Definitive	None	
Reference	Ultracentrifugation/heparin-Mn^{2+} precipitation/Abell–Kendall cholesterol (CDC)	57, 58
Routine	Chemical precipitation/enzymic cholesterol	59–62
	Homogeneous – direct	63, 64
	Agarose electrophoresis/cholesterol-specific staining/densitometry	23, 65
	LDL Cholesterol	
Definitive	None	
Reference	β-Quantification (ultracentrifugation/heparin-Mn^{2+} precipitation/Abell–Kendall cholesterol) (CDC)	15, 66
Routine	β-Quantification (ultracentrifugation/precipitation/enzymatic cholesterol)	
	Friedewald estimation	67
	Homogeneous – direct	68
	Agarose electrophoresis/cholesterol-specific staining/densitometry	23, 65
	Triglycerides	
Definitive	Isotope dilution/mass spectrometry (NIST)	69
Reference	Chromotropic acid (CDC)	70, 71
Routine	Enzymatic	72–74
	Phospholipids	
Definitive	None	
Reference	None	
Routine	Enzymatic (choline-containing), chemical, TLC, and HPLC	75–79

NIST, National Institute for Standards and Technology; TLC, thin-layer chromatography.

4.2 Preanalytical Considerations

In order to achieve accurate and precise lipid determinations, sources of preanalytical variation should be carefully monitored and controlled. Preanalytical variation encompasses biological variation (gender, age, race, physiological state), variation due to underlying pathological or physiological conditions, and those associated with specimen collection and handling. Numerous reports have underscored the significance of intraindividual biological variability in lipids.[80–82] For most lipid analytes, the mean biological CV range is 6–10%. The exceptions are TGs, which have a much higher biological variation with an average CV of 28%.[81–83] With the availability of increasingly more accurate and precise analytical methods, the preanalytical variability may have a larger contribution to measurement error than analytical variability.

Controllable factors which may have a significant impact on lipid values include body posture during blood collection,[84,85] fasting status,[86,87] capillary or venous blood sample,[88,89] sample type (serum or plasma), anticoagulant or preservative utilized, and specimen

processing and storage conditions. In addition, usual lipid status should be assessed under stable metabolic and lifestyle conditions. Blood specimens should be collected with minimal stasis after the subject has remained seated for at least 5 min.[85] A 12 h or longer fast is preferred for most lipid testing, although nonfasting samples are acceptable for TC, HDL-C, some LDL-C methods and some Apo assays.

Serum is the preferred sample type for routine analysis since the NCEP treatment guidelines are based on serum values.[3] Plasma samples, especially with ethylenediaminetetraacetic acid (EDTA) as the anticoagulant, are also used for lipid analysis. However, one must be aware of possible latent fibrin clot formation in plasma, which can be especially troublesome after freezing. In addition to venous serum and plasma, capillary whole blood may be used in portable ''point-of-care'' analyzers for lipid testing. Owing to the wide variety of point-of-care technology, the comparability of results between capillary blood and venous blood must be verified for each system.[88,89]

In addition to standardizing patient preparation and sample collection carefully, serial patient testing, at least at one week intervals, is recommended to decrease intraindividual variation by averaging several results.[81] Clinical sources of variation such as medications and underlining clinical conditions including pregnancy[90,91] should be considered when measuring lipids. Antihypertensive drugs, immunosuppressive drugs and sex hormones used in, for example, oral contraceptives and hormone replacement therapy, are known to increase lipid values.

4.3 Cholesterol

Lipoproteins have traditionally been quantified on the basis of their cholesterol content.[92] TC as well as cholesterol associated with each class of lipoprotein, i.e. cholesterol in VLDL, IDL, LDL, and HDL, can be determined either by chemical means or enzymatically. The measurement of cholesterol is performed directly on serum or plasma or after separation of the desired lipoprotein particle from other lipoproteins or biological components.

The definitive method for cholesterol determination is one employing isotope dilution/mass spectrometry (ID/MS).[93,94] This procedure was developed at the NIST, but is rarely if ever used in the clinical laboratory. The currently accepted reference procedure for cholesterol is the modification by the CDC of the original cholesterol assay of Abell, Levy, Brody and Kendall.[51,52] The Abell–Kendall reference method is based on the alcoholic hydrolysis of cholesterol ester followed by hexane extraction. The purified cholesterol is quantified by reacting with the Liebermann–Burchard (L–B) color reagent.[95,96] It has been demonstrated that the Abell–Kendall method has a positive bias of 1.6% compared to the definitive method.[97,98] The Abell–Kendall method, as prescribed by the CDC, serves as the accuracy base for the NCEP performance guidelines[5–8] used in the support of both the adult and pediatric NCEP treatment guidelines.[99,100] The CDC also serves to provide the accuracy targets for the CRMLN and the NHLBI Lipid Standardization Programs.[10]

As the Abell–Kendall procedure is labor intensive, requiring a meticulous care for detail beyond that practiced in the normal clinical laboratory setting, it is not recommended for routine use. The cholesterol esterase–cholesterol oxidase enzymatic methods are used almost universally for routine cholesterol determination, both in clinical and research laboratories. To help ensure the transfer of accuracy to the cholesterol reagent manufacturers and clinical laboratories, the CRMLN offers a certification program based on fresh serum comparisons. Thus, these samples are analyzed in the field by a specific enzymatic method and in the CRMLN laboratory by the reference Abell–Kendall method following a carefully defined protocol.

4.3.1 Abell–Kendall Reference Method

The modified Abell–Kendall assay performed according to CDC[21,51,52] protocol is linear to 400 mg dL^{-1} (10.36 mmol L^{-1}). One limitation of the method is the lack of sensitivity in the low concentration range resulting in poor precision at very low concentrations such as those encountered in some lipoprotein fractions. When performed under standardized conditions, the CRMLN laboratories routinely have CV of <1% and bias <1% of the CDC target values.

4.3.1.1 Reagents Exact protocol conditions must be followed in all steps of the procedure. Only reagent grade reagent, certified hexane and reagent grade water may be used:

- *Aqueous potassium hydroxide (33%).*
- *Alcoholic KOH (approximately 0.36 mol L^{-1})* – Prepare immediately prior to use by mixing the 33% KOH with absolute ethanol.
- *L–B reagent* – Prepare fresh by carefully combining acetic anhydride and sulfuric acid at 5 °C followed by acetic acid.
- *Cholesterol standard solutions* – Use dry cholesterol SRM911b to prepare working solutions in absolute ethanol.

4.3.1.2 Procedure Add 5 mL of alcoholic KOH to 0.5 mL of each standard, control and sample. Incubate at 50 °C for 60 min. Equilibrate at 25 °C for 10 min

with 5 mL of water, and then extract with 10 mL of hexane. Remove 2 mL of the organic phase and deliver it with 3 mL of hexane to ensure quantitative transfer. Evaporate hexane to dryness with a vacuum oven or under nitrogen. Add 3.25 mL of the L–B reagent to each of the dried extract at timed intervals. After a 30-min incubation, take absorbance reading at 620 nm at the same time intervals. The concentrations of the samples are determined from the linear regression curve for data from standards analyzed in duplicate.

4.3.2 Enzymatic Methods

For routine measurements, enzymatic methods have replaced the older chemical methods such as those employing the L–B reagents because they are easy to use, do not utilize caustic reagents and are easily automated. Most of the cholesterol measurement methods in use are based on the cholesterol esterase–cholesterol oxidase coupled reactions. These are followed by a peroxidase-catalyzed reaction resulting in a colored end-point. Unesterified (free) cholesterol can be quantified by omitting the esterase from the reagent system:

$$\text{cholesterol esters} + H_2O \xrightarrow{\text{cholesterol esterase}} \text{cholesterol} + \text{fatty acids} \quad (1)$$

$$\text{cholesterol} + O_2 \xrightarrow{\text{cholesterol oxidase}} \Delta^4 - \text{cholestenone} + H_2O_2 \quad (2)$$

$$2H_2O_2 + \text{phenolic} + 4 - \text{aminoantipyrine} \xrightarrow{\text{peroxidase}} \text{red chromagen} + 4H_2O \quad (3)$$

A wide variety of reagents are commercially available in kit format. Many are adapted to specific instruments for optimal performance and convenience. A typical cholesterol test is performed in an automated analyzer using a few microliters of sample and requires 5–10 min to complete. Throughput ranges from a few dozen tests to several hundred tests per hour. The cholesterol results are quantified from standard curves that may be stored on-line for several weeks or even months. Final results are frequently uploaded to a central laboratory computer for consolidated reporting with other test results.

While convenient and practical, the enzymatic cholesterol methods can suffer from specificity and interference problems[101] not encountered in the chemical methods. Each reagent and instrument combination including standardization must be evaluated for acceptable performance. Potential sources of variation include the source of the enzymes as well as the final component concentrations in the reagent kit. Common interfering substances in biological samples include ascorbic acid, bilirubin, hemolysis and turbidity caused by hypertriglyceridemia (lipemia). Ascorbic acid interferes in the peroxidase final step by competing with the chromagen substrate for generated peroxide. Although the normal amount of ascorbate present in clinical samples may be spontaneously oxidized before the samples are scheduled for analysis, mega doses of ascorbic acid and other antioxidants may cause difficulties.[102] Point-of-care analyzers will need to incorporate ascorbate oxidase in the reagent format as the samples (usually whole blood) are analyzed immediately after collection where atmospheric oxidation of the ascorbate will not have taken place before analysis. A comprehensive review of enzyme cholesterol methods has been published.[103]

Although the cholesterol reagent is usually purchased in commercial assay kits and measured by an automated instrument, it may be prepared in-house and analyzed manually. Nonesterified cholesterol reagent, which is not readily available in kits, may be prepared by omitting cholesterol esterase.

4.3.2.1 Enzymatic Cholesterol Reagent

- Cholesterol color reagent: an aqueous solution containing 200-mM phosphate buffer (pH 6.7), 1.6-mM 4-aminoantipyrine, 5560 U L^{-1} (enzyme units per liter) peroxidase, 400 U L^{-1} cholesterol esterase, 400 U L^{-1} cholesterol oxidase, a preservative, and a stabilizer.
- Cholesterol phenol reagent: an aqueous solution containing 40-mM phenol, a surfactant, and a stabilizer.

4.3.2.2 Procedure Add 1.0 mL of the reagent to 3.0 µL of sample. Incubate at 37 °C for 10 min. Measure the absorbance at 510 nm against a reagent blank. Lower cholesterol concentration, which requires greater analytical sensitivity, may be measured by increasing the sample-to-reagent ratio using the same esterase/oxidase reagent, or by use of an ultrasensitive reagent system, such as that used for remnant lipoprotein cholesterol measurement.[87]

4.3.2.3 Standardization Standardization of the enzymatic cholesterol reagent requires special care because the serum matrix may affect enzyme function. The goal is to assign a target value to a standard material, which usually has a different matrix from patient samples, so that the cholesterol concentrations obtained for the patient samples measured enzymatically are in agreement with those obtained by the reference methods. The CRMLN certification program was created for this purpose.[10,104]

In the 1990s, several portable cholesterol-measuring devices designed for ''near patient'' testing were introduced. These self-contained instruments for screening or monitoring generally use capillary blood obtained by

''fingerstick''. The chemistry is most often based on the cholesterol esterase–cholesterol oxidase reagent system. The accuracy traceability of these analyzers is achieved by collecting venous serum at the same time as the capillary blood is obtained. The venous serum is standardized to the reference method and provides an accuracy target for the capillary blood samples. Because of the unique design of each of these devices, careful evaluation of the performance of each device must be done before use.

4.4 Low-density Lipoprotein Cholesterol

In serum, approximately two-thirds of TC normally associates with LDL, with the remaining cholesterol residing in the two other major lipoproteins, VLDL and HDL. IDL and lipoprotein ''little a'' [lipoprotein (a) or Lp(a)] are minor lipoproteins containing relatively small amounts of cholesterol. By mass, cholesterol esters constitute approximately 38% and unesterified cholesterol constitutes 8% of LDL.[105] As for all lipoproteins, each of which consists of a complex family of rather distinct particles, LDL is generally assayed by cholesterol content. Because LDL-C is the key NCEP determinant for treatment decisions,[3,4] it is imperative that its determination be both accurate, in order to adopt the global treatment cutpoints, and precise, so that patient progress following therapy may be monitored.

To measure LDL-C, the LDL particles must be first separated from the other lipoproteins before cholesterol determination. LDL particles can be separated on the basis of such physical properties as size, charge, density or precipitation characteristics, or by Apo composition. Historically lipoprotein particles have been separated by sequential ultracentrifugation[105] and equilibrium density gradient ultracentrifugation.[106–108] These methods are labor intensive and tedious and not suitable for the routine clinical or research laboratories. Other methods of LDL-C determination include electrophoresis and chemical precipitation. Several direct measurement methods for LDL-C have been introduced. These methods incorporate the automated LDL separation in one of a series of reactions. It is important to note that most of these LDL separation methods do not distinguish IDL and Lp(a) from LDL, so LDL-C is somewhat overestimated by these measurements. However, the current cut-points for LDL-C include the contributions of the atherogenic IDL and Lp(a).

4.4.1 Beta Quantification

The term beta quantification[15,21,66] commonly refers to a procedure that combines ultracentrifugation and polyanion-mediated lipoprotein precipitation. In addition to LDL-C concentration, beta quantification also provides quantitative VLDL-C and HDL-C values. It is based on the physical separation of the VLDL particles ($d < 1.006\,g\,mL^{-1}$) from non-VLDL lipoproteins ($d > 1.006\,g\,mL^{-1}$) by ultracentrifugation of serum (density $d \approx 1.006\,g\,mL^{-1}$). VLDL and chylomicrons (if present) float to the top of the tube, producing a clear zone between the VLDL and the more dense LDL and HDL fractions at the bottom of the tube. The top and bottom fractions are physically separated by slicing the centrifuge tube with a tube slicer, followed by volumetric recovery of the fractions. Apo B-containing lipoproteins (primarily LDL) are removed from the bottom fraction by chemical precipitation. HDL-C is quantified by measuring the cholesterol content of the HDL remaining in the supernatant. By measuring the cholesterol in the $d > 1.006\,g\,mL^{-1}$ fraction (''bottom fraction''), the LDL-C can be calculated. Thus Equation (4),

$$\text{LDL-C} = \text{bottom fraction-C} - \text{HDL-C} \qquad (4)$$

VLDL-C is calculated by the difference between TC and that in the bottom fraction, Equation (5):

$$\text{VLDL-C} = \text{TC} - \text{bottom fraction-C} \qquad (5)$$

The above calculation produces a more accurate value for VLDL-C than direct measurement of VLDL-C in the top fraction as total recovery of cholesterol in the $<1.006\,g\,mL^{-1}$ fraction may be difficult in samples with high TG concentrations. The LDL-C recovered in the beta quantification method includes intermediate density lipoprotein cholesterol (IDL-C) and Lp(a) cholesterol.

Because of the heterogeneity of lipoproteins, there are many possible variations in the beta quantification procedure, each of which may affect the results. These include ultracentrifugal conditions such as temperature, relative centrifugal force and total *g*-minutes, the specific centrifuge rotor used, as well as the sample volume and the fraction recovery procedure.[109] The cholesterol analysis may be by enzymatic method or the reference Abell–Kendall method. The HDL separation may be by direct precipitation of the unfractionated sample or the $d > 1.006\,g\,mL^{-1}$ fraction using one of several available precipitation reagents. Consequently, the reference beta quantification method must be carefully standardized in order to provide consistent target values.

4.4.2 United States Centers for Disease Control and Prevention Reference Beta Quantification Method

The procedure used by the CDC has been recommended by the NCEP Lipoprotein Measurement Working Group as the reference method for measuring LDL-C. This method has served as the accuracy base for the CRMLN LDL-C certification program. To prepare the $d > 1.006\,g\,mL^{-1}$ fraction, a 5-mL aliquot of

serum or plasma is centrifuged with a 0.195-mol L^{-1} NaCl overlay at an average of 115 000 × g (40 000 rpm (revolutions per minute)) using a Beckman-type 50.3 fixed angle (20° angle) rotor. After an 18.5-h centrifugation at 18 °C, the centrifuge tube is sliced 37 mm from the bottom of the tube. The bottom fraction is then transferred to a 5-mL volumetric flask and brought to volume with 0.15 mol L^{-1} NaCl. Cholesterol in the bottom fraction is quantified by the Abell–Kendall reference cholesterol method.[21,51,52] For HDL-C measurement, the Apo B-containing lipoproteins in the bottom fraction are precipitated with heparin/manganese chloride followed by Abell–Kendall cholesterol analysis of the HDL-containg supernatant. LDL-C is calculated by the difference between the bottom fraction cholesterol and HDL-C.

The CDC reference method differs slightly from the beta quantification method used by the Lipid Research Clinics (LRC) Program,[21] which served as the accuracy base for the LRC Population Studies, a major program of the NHLBI.[110] The LRC method, which specifies fresh sera, a centrifugation temperature of 10 °C, and 0.15 mol L^{-1} NaCl overlay, yields a slightly higher LDL-C value (2–3% in samples with normal TG concentrations) than the CDC reference method.[111] Details of the CDC beta quantification procedure may be obtained by contacting CDC directly.

4.4.3 Friedewald Estimation

The majority of clinical laboratories derive LDL-C by the Friedewald estimation from TC, TGs and HDL-C. The Friedewald equation is based on the assumption that the average VLDL-C is equal to one-fifth of total TGs measured in fasting samples. Therefore, Equation (6)

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - \frac{\text{TG}}{5} \qquad (6)$$

Although acceptable for routine use in samples with TGs up to 400 mg dL^{-1} (4.52 mmol L^{-1}), LDL-C obtained by the Friedewald equation may begin to deviate from the results obtained by beta quantification when the fasting TGs are above 250 mg dL^{-1} (2.82 mmol L^{-1}).[112,113] As a rule, the Friedewald equation is not suitable for use in samples containing chylomicrons (e.g. nonfasting samples, type I and type V hyperlipidemia) and in type III hyperlipidemia because the assumption that VLDL-C = TG/5 does not apply. The Friedewald estimation is convenient and economical for routine laboratory use when TC, HDL-C and TG values are available. However, it includes the additive analytical error of the above tests and assumes that the patient has truly fasted.

4.4.4 Direct Measurements

Numerous attempts were made to measure LDL-C directly bypassing physical separation steps, such as ultracentrifugation. However, the various attempts including chemical precipitation[114] and the immunoseparation methods[115,116] have not always been entirely satisfactory. Several direct homogeneous LDL-C methods have been introduced as commercial kits.[117] These methods do not involve a pretreatment step, and are generally based on selective removal of the non-LDL particles by antibodies that specifically recognize Apos, or are based on the selective blocking of non-LDL lipoproteins followed by a LDL-selective second reagent. These methods may be automated on routine chemistry analyzers. The advantages of the homogeneous assay include the acceptance of nonfasting samples,[118] improved precision and significant labor savings. However, the homogeneous methods present a greater challenge to consistent standardization because LDL-C standards must be employed rather than simply cholesterol standards. Early results are encouraging. Long-term performance, as well as the performance in samples of unusual lipidemic and disease states remains to be established.

4.4.5 Electrophoresis

Serum lipoproteins may be separated into VLDL, LDL and HDL by polyacrylamide or agarose gel electrophoresis followed by quantification of the cholesterol with an enzymatic substrate system.[23,65] The gel composition of some products has been modified to allow separation and possible quantification of Lp(a). The electrophoretic resolution and accurate quantification of LDL and VLDL lipoprotein by electrophoresis depends on prompt analysis of the serum sample after collection. Samples with greatly elevated TGs may have poor resolution because the VLDL band trails into the LDL region. Currently the combination of ultracentrifugation and electrophoresis is the ''reference method'' for β-VLDL determination. β-VLDL particles, which are present in the <1.006 g mL^{-1} fraction and found in type III hyperlipidemia, have a β-migrating electrophoretic mobility.

4.5 High-density Lipoprotein Cholesterol

Like other major lipoproteins, HDL consists of a complex family of particles with varying lipid and protein compositions. HDL is the smallest and most dense lipoprotein, and has the highest protein-to-lipid ratio. This lipoprotein is measured by its cholesterol content, or less often by its major Apo, Apo A-I. NCEP performance guidelines for HDL-C are summarized in Warnick and Wood,[119] and in Table 2.

4.5.1 Ultracentrifugation

HDL can be separated from other lipoproteins by ultracentrifugation following adjustment of the serum density with NaBr or KBr salts to $1.063\,g\,mL^{-1}$.[120] The HDL-containing bottom fraction is quantified by its cholesterol content. The physical separation of HDL by ultracentrifugation is used primarily in research settings.

4.5.2 Chemical Precipitation Methods

The most commonly used HDL-C method in the routine laboratory has been selective chemical precipitation using a mixture of polyanion and divalent cation to remove apo B-containing lipoproteins. For this procedure, the treated serum or plasma is centrifuged and the clear supernatant is analyzed for cholesterol using a cholesterol method (usually enzymatic) optimized for the HDL-C concentration range. The most common precipitation procedures include heparin–manganese chloride,[121] dextran sulfate–magnesium chloride,[59] phosphotungstate–magnesium chloride,[60] and polyethylene glycol.[61] A number of variations of each reagent system have been developed to improve assay performance. Because of the heterogeneous nature of HDL particles, total concordance among methods is difficult if not impossible to achieve. When a precipitation procedure is employed, it is important that turbid supernatants, which indicate incomplete sedimentation of LDL and VLDL, be clarified by dilution, or by ultrafiltration using a 0.22-μm filter before cholesterol analysis in order to avoid overestimation.[59] Alternatively, the serum may be ultracentrifuged at serum denstiy to remove the VLDL and the $>1.006\,g\,mL^{-1}$ bottom fraction is processed as described above.

4.5.3 United States Centers for Disease Control and Prevention Reference Method

As with other lipoprotein measurements, the reliability of HDL-C measurement depends on both the performance of the lipoprotein separation and cholesterol quantification steps. The CDC reference method stipulates the exact conditions for both of these steps. It has served as an accuracy target for numerous population and epidemiological studies as well as the CRMLN. The HDL-C reference method, which combines ultracentrifugation, heparin–manganese chloride precipitation of the ultracentrifuge bottom fraction, and Abell–Kendall cholesterol analysis of the supernatant, is included in the CDC reference beta quantification method outlined above (see section 4.4).

4.5.4 Designated Comparison Method

A designated comparison method (DCM)[62] for HDL-C was developed by the CRMLN to provide a more practical accuracy base than the ultracentrifugation reference method. The latter requires large sample volumes, an ultracentrifuge, and is labor intensive and costly. The DCM requires a 1-mL sample and employs direct precipitation of the serum by dextran sulfate–magnesium chloride without prior separation of the HDL. However, the method is only recommended for samples with TGs less than $200\,mg\,dL^{-1}$ ($5.18\,mmol\,L^{-1}$). Samples with elevated TGs may produce incomplete precipitation of non-HDL lipoproteins, which necessitates an ultrafiltration step. The DCM is standardized to the CDC reference method. It is utilized as a reference method by the CRMLN in its HDL-C certification program.

Briefly, the dextran sulfate–magnesium chloride precipitating reagent is prepared from 50-kD dextran sulfate (Dextralip 50; Sochibo, France), reagent grade magnesium chloride ($MgCl_2 \cdot 6H_2O$) and sodium azide (NaN_3). Analysis begins with addition of 0.1 mL of the working reagent to 1.0 mL of serum. After incubation at room temperature for 10–30 min and centrifugation at $1500 \times g$ for 30 min at 4 °C, the cholesterol in the clear supernatant is measured by the reference Abell–Kendall method.

4.5.5 Homogeneous Methods

Several direct methods for HDL-C measurement have become available as commercial kits and have gained increasing acceptance.[64,122,123] These direct homogeneous methods use a small sample (10–40 μL), do not require pretreatment or prior separation steps, and can be fully automated in routine clinical chemistry analyzers. Precision values are generally excellent. Long-term accuracy, however, is dependent on the stability and correct value assignment of the HDL-C calibrators provided by the manufacturers (in contrast to the much simpler cholesterol calibrators used in the chemical precipitation methods). The homogeneous methods usually involve a first reagent which blocks the measurement of cholesterol in non-HDL lipoproteins, followed by a second reagent for HDL-C measurement.

Although extremely promising and acceptable as routine methods, the new homogeneous methods may not yield accurate results in some disease states and in samples with greatly elevated TGs.[123–125] These new methods will undoubtedly be improved with time and their overall limitations remain to be established.

4.5.6 Electrophoresis

HDL may also be separated by cellulose acetate, agarose or polyacrylamide gel electrophoresis and stained with

lipid stains such as Oil Red O or Sudan Black. The lipid bands including HDL can also be quantified by cholesterol content with an enzymatic cholesterol reagent system.[23,65]

4.6 Triglycerides

Fatty acids are the most concentrated source of biochemical energy, yielding approximately 9 kcal g^{-1} (38 kJ g^{-1}), more than twice that obtained from the metabolism of carbohydrates or proteins. As described above, fatty acids are stored and transported in the form of triacylglycerols (TGs) primarily in association with chylomicrons and VLDL.

The general approach for measurement of TGs for clinical purposes is as follows:

- TGs $\longrightarrow$ glycerol + fatty acids
- Glycerol $\longrightarrow$ intermediate
- Intermediate $\longrightarrow$ colored or ultraviolet reporter.

Although there is a definitive method established at the NIST and a recommended reference method performed at the CDC, generally, enzymatic assays are considered to be the current state-of-the-art. Enzymatic hydrolysis by a lipase to give glycerol must be quantitative, and the fatty acid composition of the TGs must be estimated. The chromotropic acid reference method used at the CDC employs synthetic standards containing a 2 : 1 weight ratio of triolein and tripalmitin. Because TG results for clinical purposes are reported in the United States in milligrams per deciliter, a difference of ~10% results if the molecular weight of tripalmitin were substituted for the weight average molecular weight of the standard triolein/tripalmitin mixture. Similarly, if the true weight ratios of the fatty acids in an actual specimen are different from those in the synthetic standards, errors result. This problem is avoided when TG concentrations are reported in millimols per liter, the Système International (SI) units.

Because up to about 3% of the acylglycerols (glycerides) in plasma are mono- and diglycerides, a small variable error occurs that is tacitly accepted. On the other hand, a variable amount of glycerol is present in serum which is also being included in the ''total TGs'' estimation in the routine laboratory. In the average serum sample, endogenous glycerol amounts to the equivalent of 5–20 mg dL^{-1} (0.06–0.22 mmol L^{-1}) TGs. Specimens from patients with certain conditions, such as in diabetes, during emotional stress or during administration of some drugs may have elevated endogenous glycerol. It is advisable to measure endogenous glycerol in such samples by omitting lipase from the reagent system and subtracting the free glycerol thus obtained from the total TG to arrive at the glycerol-blanked TG value.

Because of the wide clinical reference range of TGs [NCEP defines <200 mg dL^{-1} (2.26 mmol L^{-1}) as normal, 200–400 mg dL^{-1} (2.26–4.52 mmol L^{-1}) as borderline high and >400 mg dL^{-1} (4.52 mmol L^{-1}) as high], accurate TG determination does not have significant impact on patient care except for its role in the LDL-C estimation in the Friedewald equation.[67] However, with the advent of direct LDL assays, the usage of the Friedewald equation will decline with time. Thus, the need for correcting for endogenous free glycerol in the average patient population becomes less crucial.

4.6.1 Analytical Methodologies[126]

4.6.1.1 Definitive Method The definitive method for TG measurement is the ID/MS procedure developed by NIST.[69] This method is actually two ID/MS methods; one for total glycerides (sum of TGs, diglycerides, monoglycerides and free glycerol) and another for TGs. Currently, the vast majority of clinical laboratories measure total glycerides.

4.6.1.2 Reference Method The current recommended reference method is the chromotropic acid method preformed by the CDC. This procedure measures TGs as well as a small fraction of the mono- and diglycerides, but the mono- and diglycerides amounts to less than 1–3% of the total glyceride value. Free glycerol and phospholipids are removed in the silicic acid step of this procedure. The reaction sequence is summarized below:[70,71]

1. extraction of TG with organic solvent (e.g. chloroform);
2. removal of phospholipids by absorption on absorbent material (e.g. silicic acid);
3. saponification with alcoholic KOH to fatty acids and glycerol;
4. oxidation of glycerol, Equation (7):

$$\text{glycerol} + IO_4^- \longrightarrow \underset{\text{formaldehyde}}{HCHO + HCOOH} + H_2O + IO_3^- \qquad (7)$$

5. detection:
   (a) Hantzsch reaction, Scheme 1
   (b) Chromotropic acid (Eegriwe) reaction, Scheme 2

4.6.1.3 Routine (Enzymatic) Methods[72–74] In the clinical laboratory, serum TGs are determined using enzymatic (lipase) hydrolysis of the acylglycerols, and coupled enzymatic reactions to produce a chromophore from glycerol. The majority of clinical laboratories

Scheme 1

Scheme 2

measure all forms of glycerides (tri, di and mono) as well as endogenous free glycerol. Important examples are summarized, Equations (8–19):

1. $\text{acylglycerides} \xrightarrow{\text{lipase}} \text{glycerol} + \text{fatty acid}$ (8)

2. chromogenic step:

   (a) NADH (nicotinamide adenine dinucleotide (reduced form)) disappearance

$$\text{glycerol} + \text{ATP} \xrightarrow{\text{glycerol kinase}} \text{glycerol-3-phosphate} + \text{ADP} \quad (9)$$

$$\text{ADP} + \text{phosphoenolpyruvate} \xrightarrow{\text{pyruvate kinase}} \text{ATP} + \text{pyruvate} \quad (10)$$

$$\text{pyruvate} + \text{NADH} + \text{H}^+ \xrightarrow{\text{lactate dehydrogenase}} \text{lactate} + \text{NAD}^+ \quad (11)$$

   where NAD^+ is nicotinamide adenine dinucleotide (oxidized form)

   (b) NADH appearance

$$\text{glycerol} + \text{ATP} \xrightarrow{\text{glycerol kinase}} \text{glycerol-3-phosphate} + \text{ADP} \quad (12)$$

$$\text{glycerol-3-phosphate} + \text{NAD}^+ \xrightarrow{\text{glycerol-P dehydrogenase}} \text{dihydroxyacetone phosphate} + \text{NADH} + \text{H}^+ \quad (13)$$

   (c) quinone dye formation

$$\text{glycerol} + \text{ATP} \xrightarrow{\text{glycerol kinase}} \text{glycerol-3-phosphate} + \text{ADP} \quad (14)$$

$$\text{glycerol-3-phosphate} + \text{O}_2 \xrightarrow{\text{glycerol-P oxidase}} \text{dihydroxyacetone} + \text{H}_2\text{O}_2 \quad (15)$$

$$\text{H}_2\text{O}_2 + \text{3,5-dichloro-2-hydroxybenzene sulfonate} + \text{4-aminophenazone} \xrightarrow{\text{peroxidase}} \text{quinone dye (chromophore 510 nm)} \quad (16)$$

   (d) formazan dye formation

$$\text{glycerol} + \text{ATP} \xrightarrow{\text{glycerol kinase}} \text{glycerol-3-phosphate} + \text{ADP} \quad (17)$$

$$\text{glycerol-3-phosphate} + \text{NAD}^+ \xrightarrow{\text{glycerol-P dehydrogenase}} \text{dihydroxyacetone phosphate} + \text{NADH} + \text{H}^+ \quad (18)$$

$$\text{NADH} + \text{H}^+ + \text{oxidize tetrazolium} \xrightarrow{\text{diaphorase}} \text{reduced tetrazolium (chromophore 500–590 nm)} \quad (19)$$

Specimens for TG analysis may be serum, EDTA plasma or heparin plasma. Specimens should be refrigerated at 2–8 °C if analyzed within five days. For longer storage, freezing below −15 °C in a tightly closed container is necessary. To eliminate chylomicrons from the specimen, the patient should be fasting, ≥12 h. If postprandial specimens must be analyzed they should be well mixed immediately before analysis to accommodate expected chylomicron flotation. It should be noted that specimens from heparin-treated patients are expected to contain high levels of glycerol resulting from heparin activation of vascular lipoprotein lipase.

5 APOLIPOPROTEINS

5.1 Apolipoprotein A-I

Apo A-I is synthesized in both the gut and liver, and is secreted in the phospholipid-rich nascent HDL particles.

It performs a structural role, is the major activator of LCAT and, therefore, has a major role in "reverse cholesterol transfer" (see Kwiterovich[127] for review).

5.1.1 Standard Reference Method and Material

Apo A-I assay accuracy and precision are dependent on the availability of a pure stable reference material. Apo A-I is the first Apo for which a primary reference method has been certified. The CDC has validated an ID/MS characterization for certifying a primary reference material. A purified and lyophilized Apo A-I from the European Community Bureau of Reference, BCR-CRM 393, has been certified.[128] The WHO, based on collaborative work done under the auspices of the IFCC, and traceable to the certified reference material, selected a well-characterized lyophilized serum pool, SP1-01,[129] for the Apo A-I secondary (International) reference material. The standardization of all commercially available assays should be traceable to this material.

5.1.2 Routine Assays for Apolipoprotein A-I

Historically significant immunoassay methods that have been developed for Apo A-I include rocket electroimmunoassay, radial immunodiffusion (RID), and radioimmunoassay (RIA). Most routine laboratories use immunoturbidimetric or nephelometric assays, although enzyme-linked immunosorbent assays (ELISAs) are also available. The light-scattering assays can be performed precisely and accurately when calibrated against the WHO–IFCC international reference material. These assays, however, are susceptible to interference from sample turbidity (e.g. lipemia). This may be in part overcome by the use of detergents or lipase.[130] An additional problem with these assays is immune complex instability. This difficulty can be largely overcome by using techniques like latex particle enhancement.[131] Finally, it should be noted that production of antisera for use in Apo A-I immunoassay has been hampered by the lipophilic character of most of this protein. This leads to concealment of many potential immunoreactive sites from immunological response.[130]

5.2 Apolipoprotein B

Apo B is required for hepatic and enteric secretion of TG-rich lipoproteins. It plays a central role in chylomicron, VLDL, and LDL particle metabolism, each of which has one copy of Apo B. The Apo B in the intestinally secreted chylomicron is a truncated form of the protein, Apo B-48, while VLDL and LDL contain the larger Apo B-100. Approximately 90% of the latter are in LDL. Thus, it is closely associated with the development of atherosclerotic lesions and serves as a surrogate for measurement of LDL cholesterol.[132] It is a large molecule (550 kD), and is more hydrophobic than other Apos. During the removal of TG from its core, VLDL is progressively converted to IDL and LDL, and at the same time, a single LDL receptor-binding site becomes exposed on the lipoprotein particle surface.

5.2.1 Standard Reference Method and Material

Production of an Apo B primary reference material has been problematic because it is difficult to produce a stable lyophilized material.[133,134] However, a fresh frozen secondary reference material has been developed by comparison with Apo B isolated from freshly prepared LDL. This material, SP3-07, was evaluated by an IFCC-administered program and accepted by the WHO as the international reference material.[13] A validated ID/MS spectrometric characterization for certifying this material has not been done.

5.2.2 Routine Assays for Apolipoprotein B

As with Apo A-I, Apo B has been analyzed by immunoassay methods that include rocket electroimmunoassay, RID, RIA, and ELISA. Most routine laboratories employ immunoturbidimetric or nephelometric assays. These assays can be performed precisely and accurately, when calibrated against the WHO–IFCC international reference material. As already mentioned for Apo A-I, assays that measure immune complex formation are susceptible to interference from sample turbidity (e.g. lipemia). This may be in part overcome by the use of detergents or lipase.[130] Complex instability problems can be largely overcome by using techniques like latex particle enhancement.[131]

Apo B-48 is of interest in conditions related to postprandial chylomicronemia. This truncated form of the Apo has all of the same epitopes of the N-terminal 48% of Apo B-100. Sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE), staining and densitometry may be used to estimate it.[135] However, for routine determination, an ELISA has been developed.[136] An indirect approach to the measurement of Apo B-48 is the measurement of chylomicron remnants (see section 7.2 on remnant lipoproteins).

5.3 Apolipoprotein C-II and Apolipoprotein C-III

These two small Apos are found in chylomicrons, VLDL and HDL and play roles in regulation of the extrahepatic lipoprotein lipase. Apo C-II activates the lipase enhancing the transfer of TGs to adipose and muscle tissue. On the other hand, Apo C-III seems to inhibit the hepatic uptake of TG-rich particles.

5.3.1 Standard Reference Material

Although no official reference material is available for use in standardizing Apo C-II and Apo C-III assays, these proteins have been isolated by chromatography and electrofocusing from VLDL prepared by ultracentrifugation.[137] There does not seem to be enough interest among clinicians in the measurement of these Apos to warrant an international effort to develop primary and secondary reference materials.

5.3.2 Assays for Apolipoprotein C-II and Apolipoprotein C-III

These proteins are less hydrophobic than other Apos, and therefore antisera and monoclonal antibodies to them are somewhat easier to prepare. RID[138] is a good method for use in research studies or clinical diagnosis when relatively few samples need to be assayed. When larger numbers of specimens must be routinely analyzed, RIAs[139] or ELISAs[140–142] can be used. In addition, commercially available immunoturbidimetric assays have been developed.[143] The drawback to the latter assay is the potential for overestimation of results for turbid (lipemic) samples. This may be overcome, as described for the immunoturbidimetric assay of the other Apos, by use of detergents or lipase enzymes.

5.4 Apolipoprotein E

Apo E is a relatively small Apo that is secreted from the liver in VLDL particles. It is also found in chylomicrons, chylomicron remnants, and some subclasses of HDL, but only a very small amount is present in LDL. In addition to the hepatic synthesis, Apo E is synthesized in the central and peripheral nervous systems, and by macrophages. It is a ligand for the hepatic LDL receptor (the Apo B/E receptor) and probably for a second receptor (the LDL receptor related protein).

Apo E is found as a wild-type isoform, Apo E3, and as other two rather common isoforms, Apo E2 and Apo E4 (gene frequencies of 10% and 15%, respectively). The latter arise from two separate amino acid substitutions, causing these proteins to have altered affinity for Apo E receptors. Individuals with the E2/2 homozygous pattern of Apo E expression may have high levels of TC and TGs resulting from the accumulation of chylomicron and VLDL remnants. However, a relatively small fraction of them actually develop this type of hyperlipidemia.

The other condition associated with a common Apo E polymorphism is Alzheimer's disease. A high fraction of patients with Alzheimer's disease carry at least one Apo E4 allele.

5.4.1 Standard Reference Material

There is no official reference material for use in standardizing Apo E immunoassay. Purified Apo E for preparation of antigen for immunoassay development can be prepared by ultracentrifugation and electrofocusing.[142]

5.4.2 Assays for Apolipoprotein E

Apo E can be measured by RID, but 2–4 days is generally required.[138] RIA can be used, and, of course, it is more sensitive and rapid.[144] Enzyme immunoassays have also been developed, and are very sensitive and can be done quickly.[145] Finally, immunoturbidimetric assays have been developed and are commercially available.[146] As with other immunoturbidimetric assays, the results of this assay are compromised by lipemia. This interference is commonly eliminated by the use of detergents or lipase treatment.

The common Apo E phenotypes can be determined by various approaches to isoelectric focusing.[147–149] Genotyping can be done to give a more definite description of the genetics of Apo E isoforms. As with any genetic analyses, the reliability of Apo E genotyping requires successful DNA amplification. This can be difficult because of the very high guanine–cytosine content of the Apo E gene DNA. Once an acceptable polymerase chain reaction (PCR) product is obtained, the DNA may be analyzed by restriction fragment-length polymorphism analysis.[150] This technique usually employs polyacrylamide gel electrophoresis and visualization by ethidium bromide, but this time-consuming procedure can be replaced by automated capillary electrophoresis.[151]

6 LIPOPROTEIN PARTICLE SIZE

There is a growing body of evidence indicating that lipoprotein particle size, density and chemical composition are related to the risk of ischemic cardiovascular disease. The presence of subclasses of LDL and HDL particles has been known for some time, but with the development of semiroutine measurement techniques has come awareness of their clinical significance. It is now clear the small dense LDL is a risk factor for CHD (see Krauss[152] for a review). In addition, some HDL subclasses are correlated with the risk of CHD.[153]

6.1 Methods for Assessment of Low-density Lipoprotein Subclasses

Ultracentrifugation was first used to identify lipoprotein subclasses and this method may still be considered the

reference. One often-used approach employs a vertical rotor in a preparative ultracentrifuge.[154] One method for identifying LDL and other Apo B-containing lipoproteins uses a discontinuous salt gradient.[155]

Nondenaturing polyacrylamide gradient gel electrophoresis is the most commonly used method for determining LDL subclass size and concentration.[156] Gradients of approximately 2–14% polyacrylamide are used with the Pharmacia GE-4 or equivalent electrophoresis system.[157,158] Protein and synthetic polymer molecular weight standards are used as reference size markers. After staining, gels may be scanned and the size and amount of each subclass determined. Several LDL subclass classification schemes have been proposed. CHD risk is generally associated with subclasses below 256 Å. This LDL mobility is associated with ''small-dense LDL'' (''pattern B''), while subclasses associated with reduced mobility, the so-called ''large LDL'' (diameter > 260 Å; ''pattern A''), are associated with decreased CHD risk.[156,158]

6.2 Methods for Assessment of High-density Lipoprotein Subclasses

Sequential density ultracentrifugation is the classical method for determination of the primary HDL subclasses, HDL_2 and HDL_3.[105] This procedure has been modified to include a single centrifugation step before measurement of HDL_3-C. The HDL_3-C result combined with total HDL-C determination by standard precipitation techniques is used to determine HDL_2-C from the difference, i.e. HDL-C − HDL_3-C.[159]

Density gradient ultracentrifugation can also be used to separate the HDL subclasses in a single spin. This approach gives the major subclasses as well as some of the minor ones.[160–162] Careful attention to detail is required to obtain reproducible data, so this technique is usually reserved for use in small studies done in research laboratories.

Another approach to identifying and quantifying HDL subclasses is polyacrylamide gradient gel electrophoresis.[163] This technique identifies several minor subclasses as well as the major ones. Chromatographic methods can also be used to determine the major and some minor HDL subclasses.[164]

Routine identification and quantification of major HDL subclasses are done by chemical precipitation. Selective precipitation procedures take advantage of the HDL-subclass charge and size differences. One common method uses varying amounts of dextran sulfate and divalent cation to precipitate all the HDL in a serum aliquot, and to precipitate HDL_3 selectively from another aliquot. HDL_2 concentration is determined from the difference.[165]

6.3 Methods for Simultaneous Assessment of Low-density Lipoprotein and High-density Lipoprotein Subclasses

Both LDL and HDL subclasses may be determined simultaneously by gradient gel electrophoresis using a 4–30% polyacrylamide gradient gel that has been called a ''composite gel''.[166]

Another method for simultaneous quantification of lipoprotein classes employs a single short (<1 h) vertical ultracentrifugation step. A nonsegmented continuous flow (controlled-dispersion flow) analyzer is then used for enzymatic analysis of cholesterol in the lipoproteins present in the various fractions.[167]

A purely physical method of lipoprotein subclass analysis involves analysis of a nuclear magnetic resonance spectral fingerprint of plasma.[168] No separation of lipoprotein subclasses is employed. Rather, the methyl resonance spectrum produced by phospholipid in the outer shell of the lipoprotein in whole plasma is deconvoluted by a computerized algorithm that is based on a series of VLDL, IDL, LDL, and HDL reference spectra. This enables determination of the relative amounts of six VLDL, one IDL, four LDL, and five HDL subclasses, and allows calculation of plasma cholesterol and TG and LDL-C and HDL-C concentrations.

Specimens for lipoprotein subclass analysis should be drawn in EDTA after a 12-h fast. Plasma can be obtained by centrifugation for 20 min at 1500 *g*. Any chylomicrons must be removed by high-speed centrifugation before storage. Specimens may be stored at 4 °C for up to one week or −70 °C for longer term.

7 OTHER

7.1 Lipoprotein(a)

As described above, the atherogenic Lp(a) contains a single copy of Apo(a). Lp(a) can be quantified by measuring the total lipoprotein mass or by separating it from other lipoprotein particles and measuring its cholesterol content. The first approach requires that attention be paid to the molecular heterogeneity of Apo(a). Thus, measurement based on total Lp(a) mass, as opposed to stoichiometric measurement, may misrepresent the actual quantity of Lp(a) particles in persons carrying different isoforms of the protein.

7.1.1 Standard Reference Material

Apo(a) isolated for use in immunization animals for production of antisera for use in developing immunoassays is immunochemically different from Apo(a) in Lp(a).[169] Hence, immunoassays for Lp(a) are often developed

using the intact lipoprotein. There is currently no standardized reference material available for Apo(a), but an IFCC working group on Lp(a) is working to develop and characterize one.

7.1.2 Assays for Lipoprotein(a)

Several types of immunoassay procedure have been developed for measurement of Lp(a), including RIA,[170] nephelometric,[171] ELISA,[172,173] and immunoturbidimetric assay.[174] The latter two assays are most commonly performed. Heterogeneity in Apo(a) size can affect each of these assays. This problem is overcome in ELISA assays that use a monoclonal antibody that specifically recognizes an epitope in the region of Apo(a) that is not part of the repeat sequence found in most human Apo(a) isoforms. On the other hand, methods that rely strictly on polyclonal antibodies for recognition of Apo(a) cannot be used to assess the stoichiometric concentration of Lp(a) in serum samples.

Two assays have been developed that are based on separation of Lp(a) from other lipoproteins and estimation of the cholesterol in the isolated material. The first of these uses the binding of an agarose-bound lectin, wheat germ agglutinin, to Apo(a) to separate Lp(a) from other lipoproteins.[175] Whether the specificity of the all wheat germ agglutinin preparations for Apo(a) are equivalent, and if it binds all Apo(a) isoforms equally is not entirely clear. The assay does correlate very well with a common commercially available molar-based ELISA.

The second approach to specific measurement of Lp(a) cholesterol is more or less independent of Apo(a) immunochemistry. Thus, this procedure uses electrophoretic separation of serum components, followed by enzymatic cholesterol staining and densitometric scanning.[23,65] The method is highly automated, but separation of Lp(a) from other lipoprotein bands may be incomplete and proper selection of band area for quantification is subjective. Correlation of this method with existing commercial methods is fair.[23,65]

7.2 Triglyceride-rich Remnant Lipoproteins

TGs are primarily associated with VLDL and chylomicrons in plasma. These triglyceride-rich lipoproteins (TRLs) have been linked to pathogenesis of atherosclerosis.[176,177] However, the smaller partially catabolized TRL remnants are believed to be more atherogenic and therefore provide a better assessment of coronary artery disease risk than that provided by the measurement of total plasma TGs. Plasma TRLs of both intestinal and hepatic origins have been isolated using a number of biochemical methods and procedures based on TRL density, charge, size, lipid components and Apo composition.[178] However, because of the difficulties in isolating, characterizing and quantifying these TRLs, these methods have been primarily studied in research laboratories.

The methods most commonly used employ quantification of IDL-C in the $1.019\,g\,mL^{-1}$ ultracentrifugation-density fraction, or the measurement of β-VLDL by agarose gel electrophoresis of whole serum for comparison with that obtained from $d > 1.006\,g\,mL^{-1}$ and $d < 1.006\,g\,mL^{-1}$ ultracentrifugation-density fractions. Samples containing β-VLDL have a VLDL band with LDL-like electrophoretic mobility in the $d < 1.006\,g\,mL^{-1}$ fraction. A commercial reagent kit has been introduced that quantifies the remnant-like particles by their cholesterol content. This method is based on immunoseparation using an anti-Apo A-I and a specific Apo B-100 monoclonal antibody.[179,180] The method lends itself to automation and can be used in the routine laboratory.

7.3 Oxidized Low-density Lipoproteins and Lipid Markers of Oxidative Stress

Free radical-mediated oxidation of LDL is thought to be a major mediator in the development of atherosclerotic lesions. The presence of oxidized LDL particles in plasma has been reported to be measurable using an ELISA based on a monoclonal antibody to oxidized LDL.[181] However, it is not clear that this a viable approach for evaluating the oxidized LDL burden of a subject. A more reliable approach may be to measure the presence of autoantibodies that arise from exposure of Apo epitopes that are usually hidden from immune detection (see Craig et al.,[182] for example). Serum concentration of these antibodies has been linked to the development of coronary artery disease.[183]

The oxidative stress that an individual is exposed to depends on many factors, including nutritional, environmental, physiological and pathological conditions. Many approaches to the assessment of oxidative stress have been reported.[184,185] A promising approach for determining the overall oxidative stress of an individual is the measurement of a class of prostanoids that are formed from arachidonic acid as nonregulated, nonenzymatic free-radical reaction products. These compounds are called isoprostanes and they can be measured in plasma and urine by gas chromatography/mass spectrometry (GC/MS),[186] or immunoassay.[187] One group of isoprostanes, the F_2 isoprostanes, has been found to be elevated in individuals with hypercholesterolemia.[188]

7.4 Nonesterified Fatty Acids

Plasma nonesterified fatty acids (NEFAs or free fatty acids) have been linked to type 2 diabetes and obesity,

and indirectly with coronary artery disease. An increase in plasma NEFA is associated with insulin resistance and apparently results from failure of fatty acid transfer into adipose, muscle and other cells after hydrolysis by lipoprotein lipase.

NEFAs are analyzed by direct chemical titration,[189] HPLC,[190] gas chromatography,[191] and enzymatic analysis.[192] The latter procedure is simple and can be done on large or small scales, but it is somewhat less sensitive than other techniques and does not give information about NEFA species.

For NEFA assays to give useful information, care must be taken to prevent release of fatty acids as the result of TG hydrolysis after specimen collections. Blood specimens may be immediately transferred to ice, centrifuged at 4 °C, and stored at −70 °C until assay. Alternatively, specimens may be mixed with paraoxon, a cholinesterase inhibitor, immediately after collection.[192] However, even when the inhibitor is used, specimens should be rapidly cooled and stored at −70 °C until analysis.

ABBREVIATIONS AND ACRONYMS

AIDS	Acquired Immune Deficiency Syndrome
Apo	Apolipoprotein
CDC	Centers for Disease Control
CHD	Coronary Heart Disease
CRMLN	Cholesterol Reference Method Laboratory Network
CV	Coefficients of Variation
DCM	Designated Comparison Method
EDTA	Ethylenediaminetetraacetic Acid
ELISA	Enzyme-linked Immunosorbent Assay
EQAS	External Quality Assessment Scheme
FPLC	Fast-performance Liquid Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
HDL	High-density Lipoprotein
HDL-C	High-density Lipoprotein Cholesterol
HIV-1	Human Immunodeficiency Virus-1
HPLC	High-performance Liquid Chromatography
IDL	Intermediate Density Lipoprotein
IDL-C	Intermediate Density Lipoprotein Cholesterol
ID/MS	Isotope Dilution/Mass Spectrometry
IFCC	International Federation for Clinical Chemistry

A micro total analytical system (μTAS) is a system that enhances the performance of a complete chemical analysis by minimizing the scale on which it is performed. The main advantages are automated analyses, higher speed and better separation performance as well as the ability to analyze extremely small (picoliter) sample volumes and reactions involving minute amounts of reagents. A complete analysis may involve taking a sample, its pretreatment and separation into its different components and their detection. In order to perform this sequence of functions, the sample is transported through microchannels that connect the various system parts performing these tasks, while the various (feedback) signals are transported through a separate microelectronic network. Examples of system parts in silicon, glass and polymers that perform tasks such as hydrodynamic and electroosmotic pumping, laminar and turbulent reagent mixing and (di)electrophoretic separations of DNA fragments and particles and cells are presented. Currently, μTAS are mainly being developed and used for remote environmental and process monitoring, patient monitoring and the analysis of nucleic acids. An integrated system in each of these areas is discussed.

1 INTRODUCTION

A μTAS is a system that enhances the performance of a complete chemical analysis by minimizing the scale on which it is performed. The complete analysis may involve sampling, transport, sample pretreatment, separation into its different components and their detection. Whether stages such as sampling are part of a complete analysis will depend mainly on the practical use of the μTAS and is not very important here. To distinguish a μTAS from a chemical sensor, the requirement that at least some stages have to be integrated is useful. Moreover, the enhanced performance of the system has to be seen in its broadest sense. Not only are lower detection limits or a better sensitivity considered for better performance, but also faster or parallel analysis, less use of reagents, the possibility of continuous monitoring, remote operation or automation can be incentives for miniaturization.

Many aspects of the development of μTAS can probably best be understood by a comparison with integrated microelectronic circuits. At first sight this analogy may seem to be based on a number of more or less superficial similarities: until recently, both used silicon as their most important construction material and used lithographic methods for pattern transfer. Moreover, fluids behave in many ways like electric currents and the importance of both technologies rises exponentially. The last similarity has even prompted the extension of Moore's law to the number density and speed of on-chip DNA analyses.[1]

A somewhat closer inspection shows that the differences are manifold, however. Plastic and glass are taking the place of silicon in some μTAS applications. Whereas electronic circuits dealt until recently only with "clean" information, μTAS are in many cases supposed to deal with the dirty reality of complex samples.

Again, on a conceptual level, the similarities between the miniaturization and integration of analytical systems and electronic circuits are striking. The comparison is simplified by Table 1. It should be noted that the different approaches presented here do not mean to replace each other, they have not even been developed sequentially, and the development of some of them still goes on.

Chemical sensors form the basic μTAS components that started the development and are still important components of any μTAS. They have been in development for several decades, but never became the expected commercial success. In the early 1990s, it became apparent that for many applications, problems regarding drift, nonlinearity, calibration, but most of all selectivity would not be solved by improvements on stand-alone sensors.

A first attempt at solving these problems was made when feedback control of chemical sensors was introduced by Bergveld's group.[2] The use of feedback is a standard method in electronic circuit design to enhance the stability and linearize the response of components, as illustrated by the following example. In ion-sensitive field effect transistor (ISFET)-based urease sensors, the pH changes due to an enzymatic reaction are measured.

Table 1 Integration and miniaturization in analytical systems compared with the same trends in electronics

Electronics		μTAS
Components		Chemical sensors
Operational amplifiers	Feedback	Sensor–actuator systems
PCBs	Modular approach	MCBs
Integrated circuits	Integration	On-chip reaction, separation and detection

PCBs, printed circuit boards; MCBs, mixed circuit boards.

Figure 1 Block diagrams of (a) a conventional chemical sensor and (b) a chemical sensor–actuator system employing feedback.

Obviously, the pH changes depend on the buffer concentration of the sample, which in turn depends on the pH. Since the enzyme kinetics also depend on the pH, a very complicated nonlinear response is to be expected. By placement of a proton/hydroxyl ion actuator around the sensor, the pH can be kept at a stable value and the sensor signal used for feedback as illustrated in Figure 1(a) and (b).[3] The pH-static enzyme sensor–actuator system that was thus developed showed a linear response and had a signal that was independent of the buffer capacity of the sample. However, not all problems were solved by this approach: the sensor signal was still influenced by a deteriorating enzyme activity with time. Moreover, it turned out to be difficult to find chemical actuators besides the one mentioned above, and the cross-sensitivity remained a problem.

Traditionally, these problems were solved by a human analyst. The connection of the different steps performed by the analyst to build a system that needs no human intervention led to the development of a total analytical system (TAS), a rather bulky machine in which all the steps mentioned earlier were present.[4] The demand for portability of such machines led to the first miniaturization efforts, of which the Stanford gas chromatograph is the earliest example.[5] At Ciba-Geigy, the advantages of miniaturization for the analytical performance were systematically investigated for the first time by Manz et al.[6] At the same time that this key idea was formulated for the first time, the term μTAS was introduced.

The first systems consisted of modules performing different tasks, connected by polymer tubing, as illustrated in Figure 2. The modular approach of these systems allows the use of different materials and fabrication methods and permits separate testing of the various components, advantages that still make it a sound approach to many analytical challenges. Especially for applications such as remote sensing and environmental monitoring, where all components, including pumps and detection modules, are miniaturized, this approach is useful.

Figure 2 Block diagram of a μTAS.

The miniaturization of these systems led directly to their integration: dead volumes can be minimized and new components, only efficient at this small scale, have been developed. In contrast to the modular approach, in the integrated approach not all parts of the system are miniaturized: conventional high-voltage sources, mass spectrometers and laser fluorescence detectors are commonly used. This is because the main applications of these systems are found in laboratories for drug discovery and DNA characterization.

Two remarks on the future potential of μTAS are in place within the context of the comparison given here. First, in microelectronics, the applications surpass the original ideas of the inventors and a new engineering field has been born. Second, the use of some kind of software allows the use of the same circuit for a large number of tasks. While this step has been made in electronics, its counterpart in analytical chemistry is not apparent.

2 THEORETICAL CONSIDERATIONS ON MINIATURIZATION

2.1 Advantages

The μTAS field can be defined as exploiting the advantages of miniaturization on the analytical performance of chemical analysis systems. The effects of miniaturization on a number of key parameters in chemical analysis systems are summarized in Table 2.

As is indicated in Table 2, the Reynolds number (Re) is proportional to the channel diameter. In microchannels, Re is usually around 1500 and flow patterns are laminar under most circumstances. However, at high enough flow rates, flow can become turbulent in channels having diameters of micrometers[7] to several hundreds of micrometers.[8] On the one hand, laminar flow leads to a reproducible analytical performance that moreover can be predicted accurately by numerical calculations. On the other hand, special measures have to be taken in some cases to induce sufficiently fast mixing.

Table 2 Key parameters in the miniaturization of chemical analysis systems

Heat and mass transfer		
Reynolds number (Re)	$\frac{\text{Inertia}}{\text{Viscosity}}$	$\frac{\rho v d}{\eta}$
Weber number (We)	$\frac{\text{Inertia}}{\text{Surface tension}}$	$\frac{\rho v^2 d}{\sigma}$
Fourier number (F_o) mass	$\frac{\text{Process time}}{\text{Effective diffusion time}}$	$\frac{Dt}{d^2}$
Fourier number (F_o) heat	$\frac{\text{Process time}}{\text{Effective diffusion time}}$	$\frac{at}{d^2}$
Capillary flow	Capillary pressure	$\Delta p \propto d^{-1}$
Separation efficiency		
Electrophoresis, chromatography	Number of theoretical plates, separation time	$N \propto \frac{L}{d}, t \propto Ld$
Centrifugation	Acceleration forces	$a \propto w^2 d \propto d^{-1}$
Detection		
Volume	Fluorescence	$S \propto d^3$
Through surface	Amperometry	$S \propto d^2$
Across surface	Voltammetry	$S \propto d^0$

The Weber number (We) indicates the relative importance of surface tension effects in fluid flow. For a given liquid, We decreases with d, indicating that surface tension becomes more important.[9] On the one hand this means that narrow hydrophilic channels will fill spontaneously by capillary filling, but on the other hand that hydrophobic channels cannot be filled and (hydrophobic) gas bubbles are difficult to remove from channels.

The Fourier number (F_o) indicates the time that is needed for a concentration or heat gradient to even out. The effect of miniaturization is extremely strong here; the time needed decreases with the square of the channel

diameter. This effect makes mixing by diffusion a solution to many mixing problems and allows fast heating and cooling cycles.

The efficiencies of both electrophoresis and chromatography are most effectively described by two terms, the maximum number of plates, indicating the resolution of the separation, and the time needed to perform a separation. Both indicators are shown to improve as d becomes smaller. A good example of a fast separation was demonstrated by Jacobson et al.,[10] who performed the electrophoretic separation of rhodamine B and dichlorofluorescein in approximately 1 ms by applying a field strength of 53 kV cm^{-1}.

The efficiency of centrifuges is determined by the accelerations that they can achieve. On the one hand, the acceleration is proportional to the centrifuge radius, and miniaturization seems counterproductive. However, since the maximum allowed rotation speed of a ball bearing is proportional to its size, smaller centrifuges can rotate faster, leading to improved overall performance.

In one of their field-defining papers,[6] Manz et al. pointed out that the detection signal for a fluorescence detector is proportional to d^3, whereas amperometric signals are proportional to d^2, and refractive index and potentiometric detectors are more or less insensitive to d, where d is some characteristic dimension of the system. Obviously, as miniaturization proceeds, potentiometric detectors will become superior at some point. It remains to be seen, however, if this point will be reached in the near future; until then this is possibly the only remark in the paper mentioned above that has not been prophetic. Apart from the problems with detection that are to be expected upon further miniaturization, a sampling problem will occur when low-concentration analytes are to be determined. Obviously, at least one molecule needs to be present in the sample for detection, and in order to estimate its concentration a few tens of molecules are needed.

2.2 Modeling and Simulation for Miniaturized Total Analytical Systems

The use of modeling tools plays an important role in the design, understanding, prediction and optimization of the performance of parts of μTAS. Ideally, modeling tools should be able to predict the system performance well enough to fabricate a working device in the first process run, thus reducing the development time. Such modeling tools are not limited to the prediction of device performance, but are also used to determine the fabrication steps needed to produce a certain device.

Within the field of modeling programs for a microelectromechanical system (MEMS), recently reviewed by Senturia,[11] microfluidics is considered a ''difficult'' field because of the energy dissipation that is inherent to viscous flow and diffusion as well as the nonlinearity of chemical reactions. An extra complication, commonly occurring in other MEMS applications also, is the combination of the electromagnetic, mechanical and fluidic domain in a single device. In principle, all domains could be included in a single, larger model to be used for simulations that are very economical with regard to computation time (the Newton method). However, commonly available programs combine the effects from the various domains by solving within the domains first and then model the influence of the domains by an iterative procedure. Because of its modular set-up, this approach is easier to implement and allows the addition of new domain solvers at a later stage. However, the method is not computationally efficient, which means that only relatively simple structures can be modeled. Programs based on this method have proved to be effective for the determination of the dispersion of sample plugs in channels under hydrodynamic[12,13] and electroosmotic pumping. A number of commonly used computational fluid dynamics programs are Flowtran by ANSYS (http://www.ansys.com), Flow-3D (http://www.flow3d.com) and FlumeCAD by MEMCAD (http://www.memcad.com). Each of these has its characteristic advantages for use in a microfluidic environment. For example, Flowtran can be coupled to mechanic and electromagnetic ANSYS modules and allows the simulation of fluids having a nonNewtonian viscosity, Flow-3D allows the simulation of chemical reactions taking place in the flowing fluid and in FlumeCAD electrophoresis and electroosmotic flow (EOF) can be simulated.

The modeling of more complicated structures such as complete micropumps takes too much computation time to be modeled effectively in this way. Therefore, a hybrid approach is often more fruitful. In this approach, the various parts of the system are described by lumped elements, the characteristics of which are determined by numerical simulations or from measurements, as required. The various lumped elements are then brought together in a network and the characteristics of the network are determined by a dedicated program such as SPICE or Simulink.[14–16] An extremely simple example of this approach is the modeling of EOF in fluidic networks by electrical networks containing resistors only.

3 MATERIALS

Fabrication of μTAS is dominated by three material classes: silicon, being the most expensive and allowing the smallest structures to be made; polymers, being cheapest; and glass and quartz, playing an intermediate role. Historically, silicon is the most important material

in microsystems engineering, and many of the first microfluidic systems were made of the material.[17] However, for commercial applications, its role as a construction material is being replaced more and more by glass and especially polymers because they offer lower material and machining costs when large series have to be produced.

3.1 Silicon

Silicon is the most tried and trusted material in MEMS in general, and also in μTAS applications.[18] Because of its use in the microelectronics industry, the mechanical and electrical properties and also the etching behavior of silicon are thoroughly known. Moreover, a large number of fabrication techniques are available and the easy metallization of silicon allows on-chip electrochemical detection and the integration of a variety of optical sensors. The on-chip integration of signal processing electronics used to be an often cited reason, but this argument has moved somewhat to the background recently. Moreover, the coupling chemistry between silicon oxide and biomolecules is well developed. This advantage is of importance in the creation of enzyme microreactors,[19] which will be discussed in more detail in section 5.5. Other advantages related to microreactors are the possibility of fabricating silicon walls having a well-defined porosity by anodic etching, as described in section 4.2.1, and the high thermal conductivity of silicon, allowing the fast temperature cycles desirable for on-chip polymerase chain reaction (PCR).[20]

Silicon also has its drawbacks. For commercialization, the fact that wafers are expensive per unit area when compared with glass or plastic is very important. This high cost per unit area can be offset in principle when the devices can be miniaturized far enough, as in microelectronics. These miniaturized devices need to be fabricated by photolithography in a clean room, however, which means very high initial investments in clean room area and mask making if the devices are to be produced in-house. Alternatively, structures can be made by one of the dedicated foundries, a number of which are mentioned at the start of section 4. It should be noted that silicon can be wet-etched outside of a clean room fairly well and that the small feature dimensions, rather than the use of silicon, call for an expensive clean room and lithography equipment. Silicon templates for impression molding of microchannels having a smallest width of 20 μm have been fabricated by isotropic etching and using overhead sheets as lithographic masks.[21]

Its high electrical conductivity makes silicon less fit than plastic or glass for systems that employ high-voltage applications such as electroosmotic pumping or electrophoresis. In applications requiring smaller applied voltages, such as the free flow electrophoresis device described in section 6.4,[22] and in early electrophoretic devices,[23] a thin silicon oxide–silicon nitride film is sufficient to obtain a breakdown voltage of 100–200 V. This breakdown voltage can be increased further when the silicon at the other side of the insulating layer is removed in a subsequent etch step.[24]

Despite its shortcomings, silicon may be expected to keep its important role, especially at the research front and for the demonstration of novel concepts. Once a concept has been proven in silicon, optimization for large product series needed for commercial applications can be performed in glass and, more importantly, in polymers.

3.2 Glass and Quartz

Nowadays, glass and quartz are very extensively used in electrophoretic devices because of their good insulating properties. This allows the high electric fields (over 5500 V cm^{-1}) needed for high electroosmotic pumping rates and fast separations. Moreover, glass and quartz are chemically inert, can be sealed to silicon and are transparent, which allows the use of the optical detection methods discussed in section 7.1.

Because glass has, by definition, no crystallographic orientation, wet etching methods in glass are always isotropic. As with silicon, metallization of these materials is no problem, allowing the precise placement of electrodes for chemical detection at the end of the separation channel. Through holes for inlets and outlets can be made by ultrasonic drilling. Other advantages of glass include its chemical inertness, which makes etching slightly more complicated than the etching of silicon, and the lower cost of glass compared with silicon.

3.3 Polymers

When it comes to physical properties, polymers form easily the broadest group of materials used in μTAS. The properties that most polymers in use share and that are the key to their success in commercially oriented applications are their low cost, ease of machinability and weldability. For the construction of devices, the flexibility of the polymer is important. On the one hand, inflexible polymers poly(methyl methacrylate) (PMMA) and acrylic resins are suited for the definition of complete structures. On the other hand, flexible polymers such as poly(dimethylsiloxane) (PDMS) are generally used in combination with an inflexible polymer or glass backplate to provide the necessary support. However, difficulties have been reported with the accurate definition of channels in PDMS, in addition to problems arising from its permeability toward oxygen.[25]

4 MICROMACHINING TECHNIQUES

Over the last decade, the use of micromachining techniques in microsystems technology (MST), also called MEMS, has moved from the laboratory to the production stage. Miniaturized microphones, pressure sensors and accelerometers for automotive applications are routinely used. While μTAS fabrication technologies have a distinct character, they are commonly rooted in MST. While in MST bulk micromachining (making structures by etching into a wafer) is partly being replaced by surface micromachining (making structures by adding layers to a wafer), in μTAS there is a trend towards using new materials, most importantly plastic.

Because materials and machining are so closely related, the construction material for a μTAS has always to be chosen in combination with an appropriate micromachining technique. When a process is too expensive to be performed in-house, foundries form an interesting alternative. An example of a typical MEMS oriented foundry is MCNC, where under the MUMPs program, both micromachined and Lithographie Galvanoformung Abformung (LIGA)-processed wafer areas can be bought. A number of μTAS-dedicated foundries routinely manufacture glass chips that have customer-designed etched channels, etc. Some of the companies that are reported to perform micromachining for μTAS on a contract basis include the Alberta Microelectronics Center (http://www.amc.ab.ca) in Canada and Twente Micro Products (http://www.microproducts.nl) in The Netherlands.

4.1 Pattern Transfer

With occasional exceptions such as direct laser or electron writing, all micromachining techniques described in the following sections will etch the surface of any part of the substrate that is not protected. Photolithography permits the transfer of a pattern on to a substrate by selective protection of parts of its surface in the following manner. Photoresist [a thin, ultraviolet (UV)-sensitive, polymer film] is spin-coated on top of the substrate to be patterned, and then selectively exposed to UV radiation through a quartz slide having the desired pattern in chromium. Exposed areas of the photoresist are either made soluble (positive photoresist) or insoluble (negative photoresist) in this way. The soluble part of the resist can subsequently be removed by the appropriate developing solution. The patterned photoresist acts as an etch mask, protecting the underlying film during the subsequent etching process. Once the etching of the thin film has been completed, the photoresist mask is removed from the surface in the appropriate solvent or in an oxygen plasma. Obviously, the protecting layer has to remain intact during the etching process, a requirement that is not always easy to fulfill, especially in the more aggressive wet etchants. Therefore, the photoresist layer is often used to define a pattern in a more inert layer. Silicon oxide and nitride, chromium and gold are used to this end. The different materials used for masking will be mentioned separately for every procedure.

4.2 Wet Etching

4.2.1 Silicon

Wet chemical etching is probably the micromachining method for silicon that involves the smallest initial investment. Because it is also one of the earliest developed methods, a large number of different etch systems are well documented. Only a short outline and some examples important for microfluidic devices are given here; the interested reader is referred to the excellent book by Madou.[26]

The most important classification of these systems is by the directional dependence of the etch rate relative to the Si crystal planes: systems that have the same etch rate in all directions are called isotropic, while systems that have different etch rates for different crystal planes are called anisotropic. Examples of the latter systems are KOH, NaOH, hydrazine, ethylenediamine–pyrocathechol and tetramethylammonium hydroxide solutions. The most popular and best documented etching system is the KOH–water mixture. The reasons for the extreme difference between the slow etching {111} planes and the much faster {110} and {100} planes of Si are still unclear. However, etch rates for these planes at various KOH : H_2O ratios and solution temperatures, and also the etch selectivity relative to SiO_2 and Si_3N_4 etch masks, are well documented.[27] When these systems are used in an intelligent way, complicated structures can be realized,[28] an example of which is shown in Figure 3.

Channels that are etched by anisotropic systems usually display a characteristic and well-controlled trapezoid cross-section. The etching of channel junctions is more difficult to control and too much etching easily leads to high dead volumes in the junction. As was mentioned in section 2, some simulation tools are able to predict shapes etched in this way.[11]

For the fabrication of channels that have a (semi)circular cross-section, wet isotropic etching is more suitable. This is typically done in solutions composed of HNO_3, HF, CH_3COOH and/or water. The well-accepted etching mechanism consists in the oxidation of the Si by nitric acid, followed by its dissolution by hydrofluoric acid. The etching proceeds at the same rate in all crystallographic directions, and thus gives rise to circular etch profiles characteristic of isotropic etching. Silicon nitride etch masks are appropriate.

Figure 3 Structure showing the possibilities of anisotropic etching of silicon.

In the anodic etching process, the oxidation of the Si is achieved by application of an anodic current while the material is immersed in an HF–H_2O or HF–ethanol system. At high applied current density, the isotropic etching is complete, whereas at lower current densities porous, oxide-covered Si remains. Using this method, microreactors having porous silicon walls have been made.[19] These can be used to enhance the surface area of the reactor, as discussed in section 6.4. When the current is varied between the high and low magnitudes, empty spaces separated by porous Si can be made and concentric channels can be fabricated,[29] as shown in Figure 4.

4.2.2 Glass and Quartz

Isotropic etching of channels in glass and quartz substrates can be accomplished in stirred concentrated HF–HNO_3–H_2O (20 : 14 : 66)[30] or dilute HF–NH_4F at 50 °C.[31] Channel depths of 5.2 µm have been reported after 20 min of etching using the latter system.[32] Alternatively, buffered oxide etch (BOE) is available from Olin Hunt. While the chemical inertness of glass and quartz is a distinct advantage once the structures are finished, the etchants mentioned above have to be extremely aggressive to achieve reasonable etch rates. This means that special mask materials are needed. Masks are typically made of chromium–gold; polysilicon, which can be used in a subsequent anodic bonding step, has also been proposed.[33]

Figure 4 Concentric microchannels fabricated by anodic etching of silicon. The porous walls between the channels can be closed by an extra deposition step if needed.

4.3 Dry Etching

One of the great advantages of dry (plasma) etching is the high degree of anisotropy that can be achieved. Under the right conditions, it is possible to etch almost straight down from the substrate surface. In a standard oxygen plasma, the etching takes place due to physical milling by the oxygen ions. The etch rate can be enhanced by the addition of reactive species such as CF_3. Several micrometers of Si can readily be engraved by this method, called reactive ion etching (RIE). Recent plasma etch systems featuring higher plasma densities have been devised for the production of high aspect ratio features in silicon and in quartz.[34,35] This etching technique, known as deep reactive ion etching (DRIE), offers aspect ratios of at least 15 : 1 and a good selectivity relative to photoresist masking. Because of these high aspect ratios, DRIE reduces the substrate area needed and offers a higher design flexibility than anisotropic etching. When a combined oxygen–fluorine-based plasma is used, the balance between the etching fluorine radicals and the passivating oxygen radicals determines the degree of anisotropy of the process. In this way, vertical walls and positively and negatively tapered channel walls can be etched.[36]

4.4 Polymer Molding

Polymer molding is a technique that has relatively high start-up costs because a master template has to be microfabricated. However, once such a template is available, large numbers of chips can be fabricated, so that the variable cost per chip is acceptable. Therefore, this is a fabrication method that appears most popular for commercial applications.

4.4.1 Injection Molding

In thermoplastic injection molding, a polymer is simply heated to a temperature above its melting point, injected into the mold and cooled. This method is most suitable when large series have to be produced.

For prototyping, however, reaction injection molding is more convenient. Typically, a polymer and its curing agent are poured or injected in a mold where they are left to cure in the desired shape, which may take up to several hours. When the parts are ejected too early, sharp-edged features can become rounded, leading to a different channel cross-section than was designed. Using this method, PDMS (Sylgard 184™, Dow Corning) was cast molded in metal[37] and silicon molds,[38] both made using photolithography. The minimum dimensions that can be molded are determined by the fabrication method that is used for the master.

In order to obtain as many plastic chips as possible from the expensive silicon master template, a number of daughter templates can be fabricated from the master by nickel electroforming. Each nickel daughter can then be used for injection molding of the resin.[39]

4.4.2 Hot Embossing/Impression Molding

The hot embossing process, which is also known as ''impression molding'' or ''relief printing'' process, has been used for decades and features with sizes smaller than a micron are routinely fabricated in thermoplastic polymers by impression with a micromachined template. A well-known example is the fabrication of compact disks in polycarbonate (PC). In its most simple form, channels can be made by pressing a thin wire in a polymer chip. When two such chips are mounted perpendicularly, a very simple electrophoresis device complete with injection cross can be fabricated.[21] The quality of channels and cross-sections that are made in this way is far from perfect, however. Therefore, silicon or metal micromachined templates for complete channel structures are more useful. The fabrication of these templates is discussed in the next subsection.

Solvent-assisted molding is an interesting variation on this theme.[40] In this technique, the polymer is softened not by heating but by solvent absorption. This can be achieved by wetting a PDMS mold with an appropriate solvent and bringing it in contact with the surface to be impressed. The solvent dissolves or swells the surface and the PDMS structure is imprinted on the surface. The polymer solidifies as the solvent evaporates. Acrylonitrile–butadiene–styrene (ABS), polystyrene and cellulose acetate surfaces have been shaped in this way, using acetone as a solvent. Free-standing structures can be fabricated using this technique by shaping a thin film of photoresist and subsequently etching away the thinner part of the film.

The structures that are made by the methods described above can be used in turn as stamps for pattern transfer. This method is especially fit for the transfer of patterns having features of the order of tens of nanometers that cannot be transferred by the lithographic methods described in section 4.1. A PDMS stamp was wrapped around a cylinder to facilitate the printing process and was used for the application of masks for wet etching.[41] A PMMA film was patterned by impression molding and the impressed parts were removed by RIE and the resulting part was used for lift-off.[42]

4.4.3 Template Fabrication

The large number of different ways of fabricating templates is illustrated in Figure 5. For large structures, conventionally computer numerical control (CNC)-machined templates may be made in stainless steel. Templates having smaller structures can be made by etching of silicon. In order to facilitate the release of the polymer chips, a thin fluorocarbon coating may be applied to the silicon.[43] Anisotropically wet-etched silicon templates have been used to emboss PMMA at 135 °C for 5 min, yielding channels having a trapezoid cross-section 61.5 μm deep and 15.5 μm wide at the bottom.[21] Silicon templates fabricated by dry etching were used to emboss structures only 800 nm wide and 5 μm deep in PMMA and PC.[44]

The mold material needed depends strongly on the material that has to be molded. For example, molding of flexible polymers such as PDMS can be achieved using a photoresist template.[45] Metal molds having small features can be made by electroplating of silicon structures or thick photoresist,[43] or by LIGA, as will be discussed in the next section.

Figure 5 Micromachining techniques. Top layer: expensive single products. Middle layer: small batches of finished products and templates for the bottom layer. Bottom layer: mass production of inexpensive structures. (DEEMO: Dry etching, electroplating, molding.)

Molds do not have to be rigid, and in fact flexible templates may be at an advantage for the release of small structures and for the fabrication of structures on a nonflat substrate.[46] PDMS templates were fabricated by pouring the polymer over a chromium master. These templates were used for the fabrication of photochemically curable polyurethane (PU) structures only 8 nm wide.[47]

4.5 The Lithographie Galvanoformung Abformung Process

The LIGA process combines lithographic and molding techniques.[48,49] The lithography part is performed by X-rays making the irradiated part of a thick (micrometers to centimeters) PMMA film soluble. The X-rays are needed to provide the high energies that are needed to break the chemical bonds in the cross-links of the polymer. In the next step, the PMMA mold is filled by electrodeposition, resulting in a free-standing metal part. This part can be the end product, but may also be used in turn as a mold for the injection molding and hot embossing processes described in the previous section.

The main advantages of the method are the high resolution ($<0.2\,\mu m$) and aspect ratios, and also the smooth surfaces that can be obtained.[50] The main disadvantage is the need for a synchrotron to produce the X-rays.

4.6 Thick Photoresists

When submicrometer resolution is not a necessity, thick photoresists form an interesting alternative.[51,52] This new technology is based on an epoxy-based, thick negative-tone photoresist that can readily be patterned by classical UV sources. It is primarily composed of Shell SU-8™ Epon resin, photosensitized with a triarylsulfonium salt. Its low optical absorption in the near-UV spectrum favors good aspect ratio structures. Patterning of features up to 1200 μm in size with an aspect ratio of 18 has been demonstrated. Applications will be similar to those of the LIGA process, with a reduced resolution and aspect ratio, but at far lower cost. A number of SU-8™ applications have been reported.[53,54]

4.7 Sealing of Channels and Reaction Chambers

The fabrication methods discussed above typically provide only three walls of a channel or reaction chamber. The fourth wall has to be provided by fixing the micromachined part to a second, usually flat surface. The methods that are available to achieve this depend strongly on the materials used.

Silicon can be bonded to glass by anodic bonding.[55] Corning #7740 borosilicate glass (Pyrex®) is widely used for this purpose as its thermal expansion coefficient matches almost perfectly that of silicon. Both substrates are brought into contact and heated at a temperature in the range 350–500 °C so that the Pyrex® glass becomes slightly conductive. If a voltage between 200 and 2000 V is applied across the wafers, with the glass being biased negatively, an electrostatic force will pull both substrates into intimate contact. It is assumed that the oxygen ions leave the glass and chemically bind with Si through the formation of SiO_2. Note that anodic bonding can be used on bare silicon wafers as well as on wafers covered with thermal SiO_2, sputtered glass, polysilicon or LPCVD (low-pressure chemical vapor deposition) Si_3N_4.

By fusion bonding, Si can be bonded to Si, Si to glass, glass to glass and quartz to quartz.[56–58] The surfaces of the materials to be bonded are first hydrolyzed to create a high density of hydroxyl groups on their surfaces. Then the two parts are joined and annealed at high temperature for a long period (1100 °C for 5 h). The anneal step strengthens the bonding through a series of chemical reactions that presumably are the water formation from the OH groups, followed by its dissociation and the reaction of oxygen with Si.

Polymer channel structures can be sealed by lamination. Injection-molded acrylic chips have been laminated using Mylar® sheet coated with a thermally activated adhesive at 105 °C for 5 min,[39] while the application of poly(ethylene terephthalate) (PET)–polyethylene (PE) films at 125 °C has also been reported.[59] Alternatively, two molded plastic parts can be sealed together within less than 1 s by ultrasonic welding.[60] In this method, ultrasonic energy is brought to the contact area between the two plastic chips. When the two plastic chips to be sealed only touch in specifically designed places, energy can be delivered very efficiently to these spots only, and local welds can be made. Using this method, ABS and polystyrene have been reported for the fabrication of blood testing devices discussed in section 8.3.

Leak-free sealing of channels made of flexible polymers such as PDMS has been reported by simply placing the polymer on a glass support.[38] The resulting structures have been used for electrophoresis. Not only does this type of bonding take place immediately at room temperature, it is also reversible: the PDMS can be removed from the glass without too much trouble.

5 BASIC HARDWARE COMPONENTS

In this section, examples of a number of the basic components that can be used in microfluidic environments are discussed. For a more in-depth treatment, the reader is referred to the reviews by van den Berg et al.,[61] Elwenspoek et al.[62] and by Gravesen et al.[63] In the

literature, the parts described in this section are often given the prefix micro-. Since we deal exclusively with miniaturized components here, the prefix is omitted.

5.1 Channels, Junctions and Connectors

Channels form the backbone of any microfluidic system. In many cases, the channel is not only used for sample transport but also for separation as in electrophoresis, or as a reaction chamber. Cross-sections having a semicircular shape are routinely made by isotropic wet etching in glass, while anisotropic etching in silicon generally results in trapezoid cross-sections. The influence of the channel cross-section on the performance of the device seems to be limited, however, possibly because other problems concerning dead volume, etc., are still dominant at this point. An interesting idea that goes in an entirely different direction is the confinement of fluid streams by hydrophilic stripes on a hydrophobic substrate.[64] The fabrication of such stripes by microcontact printing, described in section 4.4, is extremely simple. However, it is far from obvious how, for example, pumping through such wall-less channels can be achieved, and no applications have yet been demonstrated.

While the fabrication of channels is straightforward, junctions may lead to dead volumes if they are not carefully designed and fabricated. Especially the connection of the μTAS device to the outside world by zero dead volume connectors is an issue that receives considerable attention. In the laboratory, connectors are often made by gluing capillary tube perpendicular to the substrate into holes connecting to the channels of the μTAS. However, such connections are difficult to align and insert, and are unable to withstand high pressures or voltages. In contrast, when the connections are properly designed and fabricated, as shown in Figure 6,[65] connectors can be made having dead volumes of less than 0.5 nl that can withstand powers up to 120 bar. The dead volume may be minimized further by etching a sleeve in the silicon connector and connection without glue is possible through the use of injection-molded couplers.[66]

Alternatively, connectors can be made parallel to the substrate.[67] This way of connecting allows a greater contact area between the substrate and the connection and is self-aligning. Moreover, concentric tubes can be connected with great ease, allowing connection to standard hollow fibers used in microdialysis.

5.2 Valves

One of the main requirements for the functioning of a μTAS is the ability to move fluid plugs over a predetermined trajectory. When electroosmotic pumping is used, the flow direction at junctions can simply be directed by application of a voltage to the appropriate channels. In contrast, pressure-driven systems need active valves that use a force perpendicular to the flow direction to push a restriction in the shape of a diaphragm or cantilever into the channel. These valves are usually made by bulk micromachining in silicon,[68] while other techniques such as LIGA[69] and polymer injection molding[70,71] are sometimes used. An important requirement in any design is whether the valve should be open or closed when the power goes down (some valves have more than one stable position). From this requirement, the valve types ''normally open'' and ''normally closed'' can be distinguished.

Figure 6 Low dead volume connection between capillary and chip. (Reproduced by permission from V.L. Spiering, J.N. van der Moolen, G.-J. Burger, A. van den Berg, 'Novel Microstructures and Technologies Applied in Chemical Analysis Techniques', *Tech. Dig. Transducers*, **1**, 511–514 (1997).)

Most active valves are micromechanics based and are miniaturized versions of macroscale valves. In these active valves, the fluid flow can be directed by piezoelectric,[72] electrostatic[73] or electromagnetic[74] actuation. Recently, two different ways of electrochemical actuation of a valve diaphragm have been proposed. The valve shown in Figure 7[75] employs the pressure that is generated when a $CuSO_4$ solution is electrolyzed, at two planar electrodes patterned by lift-off. The $1 \times 1\,mm^2$ diaphragms are made of 1-μm thick low-stress LPCVD silicon nitride or of 8-μm thick polyimide. The Cu electrode has been protected against oxygen gas with a layer of Nafion® (gel). To improve the adhesion of Nafion® on a Cu electrode, a polyimide mesh is used. The principal advantage of this system is that power is only needed to open or close the valve, but not to keep it in a stable position. This is of importance for remote devices that carry their own batteries. A second method makes use of the volume changes that occur in conducting

Figure 7 Cross-section of an electrochemically actuated active valve. The valve, which is made by bonding of micromachined silicon and Pyrex® wafers, can be used for flow regulation and uses energy only when it is adjusted.

polymer films upon cation insertion. When such a film is deposited on a thin, free-standing gold film, volume changes result in bending of the polymer–gold bilayer, as was demonstrated for polypyrrole.[76] Valves and pumps based on this principle have been proposed.[77]

An entirely different class of valves is based on properties that are characteristic for microfluidic systems only. For example, a new type of valve is formed by freezing and melting of a part (plug) of a fluid passage. This type is also called the microelectrothermofluidic (METF) valve.[78] The main advantage of this type of valve is the completely zero dead volume and absence of moving parts. A similar effect can be achieved by the use of plug of a ferrofluid that can be actuated by a magnet.[79]

An interesting example of the use of the characteristic properties of microfluidics, the simple but very effective capillary-driven valves, is worth mentioning. These valves have been used for precise positioning of sample plugs by exploiting the relative importance of surface tension in microfluidics. A change in the diameter of a channel will work as a fluid stop, and unidirectional valves can be made by giving the channel the proper shape.[80] Moreover, if the fluid is pushed through a valve by an external pressure compensating the surface tension, it will keep flowing until a next valve is met. Using this technology, complete systems can be made.[81] Because of its high surface tension, all reported devices are machined in polymers.

While active valves are mainly used to direct fluid flows at channel junctions, passive valves find their main application as check valves in micropumps, allowing fluid to flow in one direction only. Some examples are given in the next section.

5.3 Pumps

Moving fluids in the µTAS requires very precise pumping and dosing in the nanoliter range. While high pump rates may be of importance in some cases, often the reproducibility and stability of the pump rate, combined with the capability of the pump to prime itself, is of more importance. A large number of different pumps have been demonstrated over the years.

5.3.1 Micromechanical Pumps

One class employs miniaturized classical concepts using a membrane and check valves. As an example, a pump based on piezoelectric actuation of the membrane is shown in Figure 8.[82] After the initial work at the University of Twente, other groups optimized[83,84] or modified[85] the concept, and probably the most advanced micropump to date is the electrostatic bidirectional pump presented by Zengerle et al.[86] Pumps actuating the membrane by electromagnetic,[87] thermopneumatic[88] and piezoelectric[89,90] actuators have also been reported. These miniaturized ''classical'' pumps all suffer from the same problems: they have moving parts that limit their lifetime and are not very tolerant to particles in the

Figure 8 Diagram of a check-valve micropump with piezoelectric actuation.

sample stream. Moreover, they tend to produce pulsed flow patterns rather than a constant flow rate.

The problems with moving parts in valves have led to the development of pumps employing nozzles instead of check valves.[91] A pumping action is achieved because the flow restriction imposed by the nozzle depends on the flow direction, as indicated in Figure 9(a) and (b). These valves are called dynamic valves because their working principle is based on the (turbulent) fluid dynamics in the pump chamber. A similar effect can be achieved when the viscosity of the fluid is changed at the pump inlets and outlets by heating.[92] A second class of pumps relies on mechanisms that are effective in miniaturized systems only. The main advantage of these pumps, which are described below, is that they have no moving parts.

5.3.2 Electroosmotic Pumping

The most widely used pumping mechanism, EOF, relies on the presence of (immobile) surface charges on the channel wall. When a high voltage is applied the mobile counterions start to move with respect to the charged wall and drag the rest of the fluid column with them. This phenomenon is called EOF. It should be noted that this type of pump is of the ''current–source'' type. This means that the pressures that can be obtained depend on the internal flow resistance; in wide glass tubing with little resistance, very little pressure can be built up and a very small hydrostatically induced differential inlet/outlet pressure immediately overrules the electroosmotic pumping. However, in the narrow (<100 μm diameter) capillaries commonly used on chips, relatively high pressures can be obtained (up to tens of bars). Moreover, when the capillary is packed with silica beads, the surface to volume ratio of the channel increases further and pressures in excess of 8000 psi can be achieved.[93] Samples can be manipulated across junctions by application of different voltages to the ends of the respective channels, as will be discussed in section 6.3 on electrophoresis. Disadvantages of EOF pumping are the need for high voltages to achieve reasonable pumping speeds, the occurrence of electrolysis at the electrodes and electrophoretic side effects.

5.3.3 Capillary Pumping

An elegant way of pumping in microchannels is by capillary action.[94] Fluids are simply drawn at a reproducible speed into channels having hydrophilic walls. Valves for capillary pumping can be constructed in several ways, as was discussed in the previous subsection.

5.3.4 Thermocapillary Pumping

Thermocapillary pumping is used to move discrete drops rather than continuous streams through microchannels. It is based on the temperature dependence of the surface tension between the droplet and the channel wall. As one end of the droplet is heated by 20–40 °C, the surface tension at that end decreases so that the internal pressure in the droplet increases enough to move the droplet towards the cooler end.[95]

5.3.5 Electrohydrodynamic Pumping

Electrohydrodynamic pumping is of interest because it allows the pumping of fluids having a low conductivity, such as organic solvents and low ionic strength solutions.[96] The pumping activity is achieved by an inhomogeneously induced polarization of the fluid, an effect that has been known for a long time. The exact mechanism(s) involved appears to be open to discussion, however. A similar, but better understood, actuation principle is used for transport of particles and cells, where polarization differences may be expected since the fluid is not homogeneous. Advantages are the absence of moving parts and electrolysis, leading to a good sample integrity, and the absence of bubbles.

5.4 Filters

Nowadays, most current applications of μTAS are in drug discovery and genetic engineering, where sample solutions are relatively clean and well defined. In contrast,

the use of a μTAS for the on-line monitoring of industrial processes and in biofluids or waste water requires a microfilter to separate the system from the dirty ''outside world'' to prevent the blocking of channels, valves and pumps by dust particles, sand grains and living cells.

Sampling modules using conventional polymer microfilters (e.g. a Millipore™ filter) are an option. However, the anticipated problems with the large-scale integration of conventional membranes have prompted several researchers to make micromachined filters. The stream to be filtered can either flow perpendicular to the silicon substrate through etched holes,[97] as shown in Figure 10, or parallel to it through holes formed by the removal of a sacrificial layer,[98,99] as shown in Figure 11. Apart from the ease of integration, perpendicular micromachined filters can be made to have a large variety of well-defined pore sizes and shapes, extremely low pressure loss and very small internal volume. Pore diameters down to 100 nm and fluxes of 4000 $L\,m^{-2}\,h^{-1}$ have been realized.[100] On the other hand, the pore size of parallel filters is determined by the thickness of the spacer layer, which can have very small and uniform dimensions. The pressure loss across the filter can be kept low by placing large numbers of parallel filters in parallel, albeit at the expense of the increase of the dead volume.[101]

Figure 10 Perpendicular silicon microfilter, which has also been used as a mixer.

Figure 11 Planar filter made on silicon. Pore size is defined by the thickness of the separator film. (Reproduced by permission from G. Stemme, G. Kittilsland, 'New Fluid Structure in Silicon Fabricated Using a Self-aligning Technique', *Appl. Phys. Lett.*, **53**(16), 1566–1568 (1988).)

5.5 Mixers and Reactors

In a μTAS, the sample stream may have to be mixed with reagents to produce fluorescent products,[102] with enzymes or with cell lysates. In many cases this can be effectively done by a simple channel junction, but even then mixing becomes important and the channel may be referred to as a microreactor. When electroosmotic pumping is used, different mixing ratios can be realized to a certain extent by manipulation of the channel voltages.[7] When the sample streams to be mixed differ greatly in size, mixing in several stages tends to be more accurate, which can readily be achieved on a single chip.[103]

Microreactors form a fast expanding field of research, not only as μTAS building blocks, but also for the synthesis of small amounts of compounds using extremely rare ingredients, as is the case in drug discovery, or for the on-site and on-demand production of toxic or explosive chemicals.[104] Miniaturized reactors are different from macroscale reactors for a number of reasons, as described below.

5.5.1 Mass Transport

Stirring in the conventional sense is hardly possible because of the dominance of viscous effects in flow, as was discussed in section 2. Therefore, mixing in addition to chemical reaction tends to be dominated by diffusion if no special measures are taken. In many cases, this is no problem whatsoever because the distances within a microreactor can be covered easily by diffusion. If needed, there are two strategies to speed up mixing, by reduction of the diffusion distance or by induction of turbulent mass transport.

In its simplest form, the diffusion distance can be reduced by a decrease in channel width.[105] A more sophisticated way to reduce the diffusion distance is by perpendicular mixing. The experiments using this method were first performed using the perpendicular filter that was shown in Figure 10,[106] while the concept was later refined by other researchers.[107,108]

Mixing can also be sped up by inducing nondiffusional mass transport. First, at high enough flow rates, turbulence can still be induced. Extremely fast mixing, having a dead time of only 0.1 ms, has been demonstrated in ±300-μm diameter channels at flow rates of a few milliliters per second.[8] Another way to induce turbulence is by ultrasonic actuation from a piezoelectric transducer, a method that is as yet used only sporadically in μTAS,[109] but has gained much attention in other fields of chemistry.[110] Apart from a number of other effects such as the formation of hot spots, mass transfer is an important phenomenon induced by ultrasonic actuation. Acoustic streaming is induced by the sound field entering the fluid while other forms of mass transport are connected to the oscillation and collapse of bubbles that are formed by the ultrasound.[111] A second way to induce nondiffusional mass transport is by moving the fluid back and forth through a nozzle/diffuser. As was discussed in section 2.1, turbulent flow can be achieved even at these small scales. A third way to induce nonlaminar flow is by moving around discontinuous fluid plugs rather than continuous streams. The recirculation patterns developing in such plugs provide an elegant way of mixing.

5.5.2 Surface to Volume Ratio

Microreactors have a far higher surface to volume ratio than do normal reactors. Therefore, heat exchange with the surroundings is much more effective, allowing fast heating and cooling. These short temperature cycles are useful in, for example, fast PCR reactions, as will be discussed in section 8.4. Moreover, the large surface area can be used for the immobilization of catalysts, such as enzymes. For example, the oxidation of glucose by glucose oxidase (GOD) was enhanced when the enzyme was attached to 100–250-μm deep lamella or V-grooves wet etched in silicon wafers, rather than to the flat wafer surface.[112] The reactor surface area can be increased further by the anodic etching procedure described in section 3.1. GOD attached to the porous silicon resulting from this process showed an activity increase by a factor of 100.[19]

5.6 Dispensers

Although the manipulation of small volumes within the μTAS is relatively easy, bringing these volumes into the system is generally impossible using normal pipets. Therefore, structures that are able to dispense small, well-defined droplets of analyte are being developed. The design of most dispensers is based on that of commercially available ink-jet printer nozzles. The analyte droplets can be applied to an array to be analyzed later[113] or directly be accelerated into the analysis chamber of a mass spectrometer, as discussed in section 7.3. An especially interesting dispenser structure that can be inserted in the flow line of a channel structure is shown in Figure 12(a) and (b). It was fabricated by assembling a micromachined silicon nozzle to a membrane made by the same technique. Droplet volumes between 30 and 200 pL could be ejected at a maximum frequency of 500 Hz.

Figure 12 Drop dispenser that can be placed in a microchannel. In a typical application, only a small part of the fluid passing through the channel will be dispensed.

6 SEPARATION TECHNIQUES

Separations in μTAS modules have different applications, influencing the choice of the technique to be used. The dialysis and filtration techniques discussed in section 6.1 are mainly used to prevent the malfunctioning of the μTAS device owing to obstruction by particles, cells and dirt. In order to fulfil this task, at least one side of such a filtration or dialysis module needs to be able to withstand the conditions it has to keep out of the system. Other separation techniques are focused on the separation of a sample into its different components, allowing subsequent analysis. The requirements of devices performing these functions are totally different from those performing the first.

6.1 Dialysis, Filtration and Centrifugation

The rationale behind dialysis and filtration as a first step in a μTAS was explained in section 5.4. In microdialysis sampling, polymeric hollow-fiber membranes are used to separate large biomolecules and cells from the analyte. This technique, introduced about 10 years ago, has now become a standard technique in neurochemical laboratories.[114] These hollow fibers have been integrated with biosensors[115,116] and serve as sample cleanup modules for mass spectrometry (MS).[117] Because the smallest fiber diameters available today are rather large (200 μm), a counterflow dialysis module was micromachined by sandwiching a dialysis membrane between two polymer chips that had laser-ablated channels in their surface.[118]

Whereas many filters have been proposed and developed, actual ultrafiltration modules have not, to our knowledge, been applied in actual systems.

As was discussed in section 5.5, the strictly laminar flow in microfabricated channels makes diffusion play an important and reproducible role in mass transport. The diffusion coefficient increases with increase in molecule size, permitting separation methods based upon the diffusion speed, and thus on molecule size, without the use of a membrane.[119] Obviously, the method is most effective when the fractions to be separated have very different diffusion coefficients. The principle has been demonstrated, but accounts of actual separations are still to be published. Both sides of this separation unit are connected to microchannels and therefore the method is probably less suited for precleaning stages.

Moreover, obstacle courses for the trapping to branched DNA molecules[120] have been developed on-chip.

Centrifugation is a very effective way to separate particles and cells from fluids as a precleaning step, especially for DNA analysis, where the cells contain the sample. At first sight, centrifuges may not seem likely candidates for miniaturization; in Table 2 it was shown that the separation efficiency of a centrifuge is proportional to its diameter. However, the speed rating of a bearing is proportional to its size, so that smaller centrifuges can be run at higher speeds. Using conventional machining techniques, an 8.6-mm diameter microcentrifuge was built that allows 40 times faster separations than conventional centrifuges.[121] The centrifuge is of the flow-through type and can be used in arrays compatible with standard 96-well microtiter plates.

6.2 Chromatography

Gas chromatography (GC) is the first analytical procedure that was performed on a chip, at least 10 years before the μTAS concept began to take shape.[5] The advantage of miniaturization of the chromatograph was believed to be its reduced size and weight, rather than its improved analytical performance. Recently, however, a 10 μm × 100 μm × 2 m on-chip separation column was demonstrated that does exhibit a separation performance that is superior to that of a conventional column.[122]

In contrast, when Manz et al. fabricated their first on-chip open-channel liquid chromatograph, the μTAS concept had just started to develop.[17] Their chromatograph employed a normal off-chip high-performance liquid chromatography (HPLC) pump, a 6 μm × 2 μm × 15 cm channel, anisotropically etched in silicon, and on-chip conductometric detection. Later, the reversed-phase separation of coumarin 440, 450 and 460 was demonstrated using an open channel etched in a glass chip with on-chip electroosmotic pumping and off-chip laser-induced fluorescence (LIF) detection and 4–5-μm plate heights were realized.[123] The use of conventionally packed columns is complicated by the nonuniformity of the packing at the channel walls (the increase in surface to volume ratio upon miniaturization is a disadvantage in this application). This problem can be solved by micromachining the ''column packing'' in addition to the channel walls. Recently, RIE has been used for the fabrication in quartz of the collocated monolith support structures (COMOSS) shown in Figure 13(a) and (b).[124] The separation efficiency of rhodamine 123 in reversed-phase coated structures of this type was 35 000 plates ($h = 1.29\,\mu m$).

6.3 Electrophoresis

Capillary electrophoresis (CE) is the most commonly used separation technique in μTAS today. The great separation efficiency, the absence of moving parts to induce fluid flow and the availability of electrophoretic schemes for on-chip sample injection and addition of reactants make it an exceptionally potent technique. There are many excellent books introducing the broad field of electrophoresis, and one of the most recent has a separate chapter discussing on-chip electrophoresis.[125] The interested reader is referred to these for a more in-depth treatment of this subject. Compared with CE, on-chip electrophoresis can be faster and more efficient when short separation distances and high separation fields are combined with very short injection plugs and integrated detection systems.

Briefly, electrophoretic separations are achieved by application of a high voltage between the two ends of a liquid-filled channel, so that each individual molecule inside the channel migrates in the electric field according to its own mobility. The mobility of the ions decreases with the ratio of their mass to charge (m/z) so that small, highly charged molecules reach the end of the channel before larger, singly charged molecules. When

Figure 13 COMOSS, part of a micromachined liquid chromatography (LC) column. (Reproduced with permission from B. He, N. Tait, F. Regnier, 'Fabrication of Nanocolumns for Liquid Chromatography', *Anal. Chem.*, **70**(18), 3790–3797 (1998).)

the separation is efficient, concentrations of the different molecules are detected as Gaussian peaks having a standard deviation σ. When the m/z values of the different molecules are known, a single, nonspecific detector can be used to distinguish between the different molecules present. As an example, on a capillary gel electrophoresis chip that was optimized with respect to separation efficiency, separations having efficiencies of $N = 200\,000$ ($h = 0.24\,\mu m$ at $L = 70\,mm$) were realized within 5 min.[126] The separation efficiency is determined by the following factors:

- the length of the injected sample plug;
- the length of the area sampled by the detector;
- the diffusion of the ions during the separation, which is increased by Joule heating.

Because on-chip separations usually involve relatively short separation times, the diffusion is relatively unimportant. The detector length is only of some importance in ultrafast (<150 ms) separations in extremely short (900 μm) channels.[127] In all applications, the length of the injected sample plug plays the most important role and should be kept as narrow as possible. There has been a steady development in injection schemes. The first injections, into a simple T-junction where a voltage is applied to two channel ends while the third is floating,[128] were reproducible to within 3%,[129] but suffered from mobility bias (highly mobile ions are over-represented in the sample), from leakage from the floating channel and from peak broadening.[30] Various solutions to the problem have been demonstrated. More sophisticated junction layouts, such as double T-junctions,[130] and more sophisticated voltage control of all side channels[131] have enabled the separation efficiencies mentioned above to be achieved.

CE has many different specialized varieties, and a number of these have been demonstrated on chip, including isotachophoresis (ITP),[132–134] isoelectric focusing (IEF),[135] gel electrophoresis[136] and micellar electrokinetic chromatography (MEKC).[137] Of these methods, gel electrophoresis is the most extensively used because of its usefulness for the separation of DNA fragments.

The detector measures a sequence of separated sample components during a certain time window, which makes the method unsuited for on-line monitoring. This problem has been addressed by moving the output of the electrophoretic channel by a stepper motor along the 15-mm side of a 21 μm × 15 mm × 48 mm channel.[138] At the other end of the channel, a 100-electrode-wide amperometric sensor array served as a detection unit. The electrode number provided a measure of the position along the channel side, which could be translated to a certain sampling moment.

6.4 Sorting and Manipulation of Large Biomolecules, Particles and Cells

One of the frequently cited advantages of μTAS is the avoidance of contamination of analyses by on-chip sorting of the relevant cells from a culture, cell lysis, DNA amplification and analysis. A number of these devices are discussed in section 8.4.[139] However, the on-line sorting and manipulation of cells received little attention until a few years ago.

The behavior of cells in constrained environments is complicated. However, the assumption that they behave as particles of the same size is good enough for most of the applications discussed here. The electrophoretic motion and manipulation schemes used for high-molecular-weight samples can be used for whole cells[140] and large

molecules or particles are often used as model systems for cell manipulation.

One way of sorting large biomolecules is by free-flow electrophoresis: a sample stream is fed into the structure. A voltage is applied between the left- and right-hand sides of the cell so that, as the stream flows from the top to the bottom, the sample is separated according to its electrophoretic mobility. A certain fraction of the sample can be led to a unit for continuous detection. Such an on-chip system was demonstrated to be competitive with a commercial instrument for the separation of large biomolecules and protein tryptic digests and for the purification of whole rat plasma.[22]

Cells have also been separated by exploiting their differences in polarizability.[141] A mixture of cultured human breast cancer cells and normal human peripheral blood cells was led over an interdigitated electrode array that actuated an upward dielectrophoretic force to the cells. The cells moved upward until the dielectrophoretic force, which decreases with increasing distance from the electrodes, was balanced by gravity. Because of their different polarizabilities, different cells experience different upward forces and will have different equilibrium heights with respect to the electrode array. Because the horizontal flow rate depends on the distance from the channel wall, the height difference is translated to a mobility difference and separations of different types of cells can be achieved.

In order to minimize the sticking of cells to channel walls, dielectrophoretic forces have also been used to manipulate cells without the use of channel walls. Funnels and also channels and switches based on dielectrophoretic forces have been developed.[142] Alternatively, a checkerboard pattern of electrodes that allowed the actuation of fields in different patterns was used for cell separation. In order to minimize contact between the cells and electrodes, a gel coating was applied to the electrodes in this experiment.[143] The same actuation method was combined with optical radiation pressure manipulators for the noncontact manipulation of *E. coli* cells.[144]

7 DETECTION

In drug- and DNA-related applications, detection is one of the least integrated parts of μTAS. Optical detection schemes such as LIF are compatible with the disposable chip format without integration. Therefore, at the moment LIF detection is by far the most popular detection system in this field. However, in applications where portability is an issue, integration of the detection on the chip is an important requirement. Therefore, alternative detectors have also been investigated. Moreover, as was indicated in section 2, as the trend of miniaturization proceeds, electrochemical sensors become more sensitive than optical detection schemes. Finally, a few examples of detection by MS are given to illustrate its capability to identify large biomolecules.

7.1 Optical Detection

Optical detection schemes, especially LIF, are dominant as far as chip-based systems are concerned. In the channel, a 50–200-μm spot is exited by a focused laser beam and emitted light is collected by a lens system and detected by a photomultiplier tube. Although numerous detection schemes are available,[145] most optical detection systems in μTAS applications simply measure changes in fluorescence intensity. An interesting exception is an integrated system developed by Evotec Biosystem (http://www.evotec.de) that allows the use of a number of different techniques. For example, fluorescence correlation spectroscopy (FCS) is employed to determine the diffusion coefficients of fluorescent molecules. Since the diffusion coefficient depends on the size of the molecule, molecular binding events and also the activity of restriction enzymes[146] and conformational changes of molecules[147] can be detected. Other optical detection schemes that have been used for on-chip detection include UV absorption[125] and Raman spectroscopy,[148] which is interesting because of the compound identification capabilities it shares with MS.

As an alternative to the laser and photomultiplier set-up, less expensive light-emitting diode (LED) and photodiode systems have been used to validate theoretical dispersion models.[12,13] Similar systems have been integrated in a system for the detection of orthophosphate, where fiber optics were used to direct the light,[149] and in the MCB demonstrator described in section 8.2.[61]

When optical detection is performed perpendicularly to the channel, the fluorescent signal decreases quickly with decreasing channel diameter and scattering at the channel walls decreases the signal-to-noise ratio. These problems have been reduced by fabrication of specially designed detector cells. In its simplest form this can be a loop in the channel to which optical fibers are fitted.[150] The sensitivity of the system was reported to be 10 times better than that of perpendicular detection because of the increased path length of the light in the channel and the decrease of scattering phenomena. Alternatively, the optical path length is increased when the light beam is introduced at an angle, so that reflections at the channel walls allow it to travel a number of times back and forth before detection. A silicon detection cell employing this method was constructed, but the losses occurring at each reflection led to disappointing efficiencies.[151] Problems of this kind can be avoided by integrated optics, a good example of which is the channel wall integrated

evanescent wave detector.[152] In this detector, a large number of reflections occurs and the evanescent part of the light wave is influenced by molecules adsorbed at the channel wall at each reflection. The sensor signal is expected to be independent of the channel diameter for channels wider than approximately 2 μm.

For the observation of flow patterns in channels and at junctions, charge-coupled device (CCD) cameras are used, because these systems are especially suited for the simultaneous optical detection at different positions in a system. This advantage is exploited in an interesting way in a device called the T-cell. These structures are deliberately designed so that mixing across the channel diameter is incomplete. This allows the measurement of background and calibration signals at the same time as the sample signal detection.[153]

7.2 Electrochemical Detection

Whereas optical techniques are commonly used for the off-chip detection of on-chip separations, electrochemical methods are more promising for integrated detection. Using standard lithographic and integrated circuit compatible methods for the fabrication of microelectrodes[154] and field effect transistor (FET) structures,[155] a wealth of inexpensive continuous detection schemes are available. Especially amperometric detection schemes have been developed for combination with LC and CE[156] because of the potential of their superior sensitivity. Methods for the wafer-scale fabrication of the membranes that are needed for the fabrication of ISFETs[157] and enzyme electrodes[158] are available. The range of compounds that can be detected is broadened even further when electrochemically active reagents are added. For example, DNA fragments separated by CE were detected using on-chip amperometry by addition of electrochemically active intercalation agents.[159] Moreover, an amperometric electrode array was described that permits time-resolved detection from continuous electrophoretic separations.[160] Although such a set-up might also be realized using a CCD camera, the strength of electrochemistry for parallel data acquisition is demonstrated by this method.

When electrochemical detection schemes are to be combined with CE, special measures are needed to minimize the interference of the detection module by the electrophoretic high-voltage part of the system. This was achieved by placing the detector electrodes directly behind the separation electrode.[159] In order to decrease the electric field in the detection region, the channel was widened at the detector position.

Electrochemical detection has proven extremely useful in portable applications for environmental[161] and point of care (POC) clinical monitoring. A μTAS for bedside monitoring of patients has been developed that offers a good example of the possibilities of electrochemical detection.[162] It employs potentiometric detection to measure sodium, potassium, chloride, ionized calcium, pH and pCO_2, while urea is detected by potentiometry after an enzymatic reaction, glucose and pO_2 are determined by amperometry and hematocrit is detected conductometrically. This μTAS will be described in more detail in section 8.3. In another system for continuous monitoring of patients, pH and pCO_2 detectors based on ISFETs were used in combination with an amperometric O_2 sensor.[163] Alternative possibilities demonstrated for on-chip electrochemical detection include stripping voltammetry,[164] coulometric titration[25] and redox-sensitive FETs.[165] The last devices are especially interesting because they contact the sample in only one spot,[166] minimizing noise and eliminating the need for a reference electrode.

7.3 Mass Spectrometry

In recent years, MS of biomolecules has received a lot of attention[167] because of its enormous fingerprinting capabilities. In electrospray ionization mass spectrometry (ESIMS), the most commonly miniaturized format, the analytes that are leaving the on-chip separation channel are directly ionized and accelerated towards the mass spectrometer.[168] When the detection and identification power of MS is combined with the separation efficiency of electrophoresis, a system can be built that allows the selective determination and identification of all compounds in a complex biological sample. Direct coupling of the mass spectrometer to a CE-based μTAS has been reported by several researchers.[169,170] Absolute detection limits as low as 1 fmol and concentrations at the 1 nM level combined with identification of the compounds have been reported.[171] Multichannel chips were used to analyze sequences of up to five samples from one chip.[170]

8 APPLICATIONS

In this section, four examples of a μTAS are given that are to perform completely different analyses in completely different environments. As a result, the functionality of the devices is also very different, thus giving a good overview of the scope of μTAS. In Table 3, the similarities and differences are summarized.

8.1 Continuous Blood Monitoring

The continuous monitoring of basic parameters such as pH, pO_2, pCO_2, potassium and sodium in blood was

Table 3 Requirements in different fields of μTAS

Field	Size	Robustness	Maintenance	Integration
Continuous blood monitoring	Portable by patient	High	Hours/days	Zero/low
Environmental and process monitoring	Portable	High	Weeks/months	Intermediate
Bedside blood monitoring	Portable	Intermediate	N/A	Intermediate
On-chip DNA characterization	Laboratory	Low	Minutes	High

one of the first challenges that was met by μTAS. The requirements of such systems are severe: since the system has to be carried on the patient, miniaturization of the complete system is needed. Moreover, frequent calibrations are needed to correct for signal drift due to the fouling of the sensor surface that is common with biological fluids.

A flow-through cell containing a pH ISFET and reference electrode, four miniaturized Clarke-type amperometric dissolved oxygen sensors and two ISFET-based Severinghaus-type potentiometric CO_2 sensors was fabricated at the University of Neuchâtel.[163] All sensors were made on a single 22×6 mm silicon chip that served as the bottom of the flow cell. Al_2O_3 was used as a pH-sensitive gate material on the ISFETs, that showed a sensitivity of 51 mV pH^{-1}. It would be inappropriate here to describe the fabrication of the ISFET sensors, and the interested reader is referred to an extensive description by Bergveld and Sibbald.[172] The Ag/AgCl reference electrodes were fabricated by galvanostatic growth of a 20-μm-thick Ag layer on a thin-film Pt electrode and subsequent chlorination in 0.1 M KCl. The Ag layer was made this thick in order to improve the lifetime of the electrode. The oxygen sensor had an amperometric three-electrode set-up consisting of a Pt microelectrode array, Pt counter electrodes and a reference electrode that was made as described above. A sensitivity of 0.36 nA $Torr^{-1}$ (1 Torr = 133.3 Pa) was achieved.

The CO_2 sensor used an Al_2O_3 ISFET to measure the pH change in a pocket of internal electrolyte that is induced by the dissociation of CO_2 into carbonic acid. A sensitivity of -39 mV $(pCO_2)^{-1}$ was reached. In order to provide the internal electrolyte where needed, all sensors except the pH ISFET were covered with a UV-curable polyacrylamide hydrogel and a polysiloxane gas-permeable membrane to provide an inner electrolyte. A 600-μm-high polysiloxane ridge and glass cover completed the flow cell.

Although the resulting structure had a functional lifetime of more than 5 weeks, the calibration problem was not solved. A calibration concept was demonstrated in a flow cell containing potassium-sensitive chemically sensitive field effect transistors (CHEMFETs).[83] Sample was pumped from a stream into a channel by a piezoelectrically actuated silicon micropump. The CHEMFETs were placed between the channel entrance and the pumps, and care was taken not to pump the sample all the way to the pumps. In this way, the pumps were only in contact with the clean internal solution and pump blocking by particles and dirt was avoided. A second pump was used to pump a calibration solution to the detector. The dead volume of this modular system was still rather high at 5 μl, leading to lag times of several seconds. This concept is developed further in the next subsection.

8.2 Environmental Monitoring

For environmental monitoring, the constraints on the size of analysis systems may be less severe than for continuous blood monitoring. At the same time, the level of system integration tends to be higher, because the analyses often have to be carried out in remote and difficultly accessible places, so that units must be able to run untended for weeks or even months. Because response times tend to be of less importance, remote environmental monitoring is extremely fit for a μTAS based on the modular approach.[173] The MCB concept, adapted from the PCB used in the electronics industry, is a good example of this approach, developed at MESA.[61] An MCB combines electric wiring connecting the electronics needed for data acquisition from the sensors and pumps drivers with fluid circuits connecting the different modules present on the board.

As a demonstration, the system shown in Figure 14(a) and (b) was developed. It consists of three inlets/outlets, two micropumps, two flow sensors and an optical absorption detector module. It can be used to measure chemical reaction products by detection of the (spectral) absorption intensity. Sample and reagent liquids are mixed in the appropriate amounts on-board (the actual mixing takes place during the propagation in channels) and the optical intensity from different colored LEDs is measured by a 64-pixel CCD detector.

The electronic control circuitry is situated in two levels below the fluidic circuitry layer with the modules. It is based on a microcontroller system for the microliquid handling and the chemical analysis data. Implemented in the electrical circuitry are driving circuits for the micropumps, sensing circuits for the flow sensors, optical absorption measurement circuitry, power management and communications using an RS232 interface.

Figure 14 (a) MCB layout and (b) actual device.

A system for automatic groundwater analysis that is to be part of a monitoring network using radio communication has been realized.[174] The system uses ion-selective electrodes to measure nitrate and potassium while a microspectrometer combined with photometric reagents is used to determine iron levels. Microfluidics, including a mixer, were realized by anisotropic etching of p{100} Si in KOH and anodic bonding to Pyrex®. The whole system is mounted on a 75 × 500 mm board, which is rather large. However, it should be noted that everything needed, including tanks filled with calibration fluid, are included on the board.

8.3 Intermittent Bedside Blood Monitoring

Although continuous blood monitoring is still in the research phase, at least one intermittent real-time bedside blood monitoring system is commercially available. Not only is this system an improvement on traditional analyses by a central (hospital) laboratory because the test can be performed before the hospital is reached and results are available within 1 min,[175] but also the immediate analysis also guarantees that a fresh blood sample is used.

A complete blood analysis system was developed by I-STAT (http://www.i-stat.com).[176] The central part of the system is a disposable card consisting of two molded polymer structures sealed by a double-sided adhesive sheet. In this card, a droplet of whole blood is transported by capillary pumping into a channel until a capillary valve described in section 5.2 is met. When a reproducible amount of sample is taken in this way, the channel is sealed off and the card is placed in a hand-held analyzer. A pouch containing calibration fluid is pinched by a barb that is part of the card, and the fluid is led past the sensors. When the sensors are calibrated, the sample is led past the same sensors by operation of an air bladder. Sodium, potassium, chloride, ionized calcium, pH, pCO_2, pO_2, urea, glucose and hematocrit are all detected by a variety of electrochemical detection schemes, as described in section 7.2.

Although the card is at the center of the system, the latter would not function without the development of complementary technology. The analyzer is made to store patients' records and to acquire data. In order to allow electrochemical detection within 1 min after the sensors are wetted for the first time, a method to perform the

analysis before the electrodes have reached equilibrium was developed.[177]

8.4 On-chip DNA Characterization

In on-chip DNA analysis, portability is not an issue and miniaturization efforts are directed towards fast, high-resolution separations and integration. At present integration of detection modules or reactant reservoirs is not believed to lead to significantly better system performance. In contrast, the minimization of dead volumes and maximization of separation speed by miniaturization is given priority. In order to maximize the number of separations even further, chips having a large number of parallel channels are being developed.[178] However, as miniaturization proceeds and the amounts of substances to be detected become smaller, the integration of smaller detection units in DNA characterization chips will be needed to obtain acceptable signal-to-noise ratios.[139]

The usefulness of on-chip electrophoresis as a separation method for DNA characterization first became apparent when the separation of amino acids in open channels on glass chips was demonstrated.[129] Subsequently, channels on thermally bonded glass chips were filled with a sieving matrix and ultrafast (2 min) DNA fragment separations were demonstrated.[179] Although many variations on this theme have been performed since then, the set-up has remained the same in most cases: only the glass chip is miniaturized and detection and high-voltage modules have conventional sizes.[123–131] Later developments include various on-chip mixing schemes, including pre- and postseparation mixing of fluorescent labels,[32,57,102] mixing of the restriction enzyme with complete DNA molecules[180] and mixing of cells and lysing agents.[181] Lately, good results have been obtained with cheaper polymer chips.[38,39]

Moreover, the advantages of fast heat diffusion from miniaturized devices have been demonstrated by on-chip PCR amplification. Silicon reaction chambers with integrated heaters have been reported by several groups.[20] The high surface to volume ratio of the chambers allows the application of fast heating and cooling cycles of the order of 1 min.

In an alternative set-up, on-chip PCR amplification was performed by pumping the sample through a channel meandering across three thermostated temperature zones on a glass chip.[182] The number of meanders traveled by the sample plays the same role as the number of temperature cycles in conventional PCR. Because of the small channel diameter, heat dissipation was very fast and both heating and cooling times were below 100 ms. Because the first part of the meander is never in contact with the amplified, more concentrated DNA, cross-contamination seems less likely when this format is used compared with batchwise PCR reactions.

Although most research is still done on system components, (partly) integrated systems are beginning to appear in the literature[138,180] and are being brought on to the market by Cepheid (http://www.cepheid.com). A system reaching a high level of integration was recently presented by Mastrangelo's group. In their system, integration of components for sample loading, drop metering, PCR amplification, electrophoresis and photodetection into a microfluidic circuit was demonstrated.[95,183] The device was made in silicon and glass and employed an external pressure source for fluid motion, and hydrophobic patches were used to direct the fluids.[80,184]

ABBREVIATIONS AND ACRONYMS

ABS	Acrylonitrile–Butadiene–Styrene
BOE	Buffered Oxide Etch
CCD	Charge-coupled Device
CE	Capillary Electrophoresis
CHEMFET	Chemically Sensitive Field Effect Transistor
CNC	Computer Numerical Control
COMOSS	Collocated Monolith Support Structures
DRIE	Deep Reactive Ion Etching
EOF	Electroosmotic Flow
ESIMS	Electrospray Ionization Mass Spectrometry
FCS	Fluorescence Correlation Spectroscopy
FET	Field Effect Transistor
GC	Gas Chromatography
GOD	Glucose Oxidase
HPLC	High-performance Liquid Chromatography
IEF	Isoelectric Focusing
ISFET	Ion-sensitive Field Effect Transistor
ITP	Isotachophoresis
LC	Liquid Chromatography
LED	Light-emitting Diode
LIF	Laser-induced Fluorescence
LIGA	Lithographie Galvanoformung Abformung
LPCVD	Low-pressure Chemical Vapor Deposition
MCB	Mixed Circuit Board
MEKC	Micellar Electrokinetic Chromatography
MEMS	Microelectromechanical System
METF	Microelectrothermofluidic
MS	Mass Spectrometry
MST	Microsystems Technology

PC	Polycarbonate
PCB	Printed Circuit Board
PCR	Polymerase Chain Reaction
PDMS	Poly(dimethylsiloxane)
PE	Polyethylene
PET	Poly(ethylene terephthalate)
PMMA	Poly(methyl methacrylate)
POC	Point of Care
PU	Polyurethane
RIE	Reactive Ion Etching
μTAS	Micro Total Analytical System
TAS	Total Analytical System
UV	Ultraviolet

The recent introduction of powerful methods for the analysis of nucleic acids has started a revolution in medicine, opening up a new field of molecular diagnosis. The core technologies of molecular diagnosis involve techniques for the amplification and characterization of nucleic acids. These techniques have enabled the diagnosis of many diseases with unprecedented sensitivity and specificity. As research tools, these methods have increased our understanding of many diseases on a molecular level, with the unraveling of the molecular pathology of many common disorders. Foundation for the rapid and continual development of molecular pathology into the next century has received a boost from the Human Genome Project (HGP), which is expected to be completed over the next few years and which will provide the essential genetic blueprint for future investigations.

1 INTRODUCTION

Molecular biological analysis is the use of analytical procedures aimed at the elucidation of the chemical and physical basis of biological systems, especially with regard to the structure and function of genes. Many of the procedures in molecular biology are concerned with the manipulation and characterization of nucleic acid species, especially DNA and RNA. One advantage of molecular biological analysis is that a standard set of techniques can be applied to numerous biological systems because the target materials are mainly nucleic acids. A second advantage is the exquisite sensitivity of many molecular biological techniques.

Molecular pathology is the use of molecular biological techniques towards the understanding of the etiology and pathogenesis of diseases, and the development of diagnostic tests for these disorders. As proteins are the ''downstream'' products of the information flow from DNA to RNA to protein, the understanding of the aberration of ''upstream'' elements (i.e. DNA and RNA) in this pathway can improve our fundamental understanding of many diseases. Such improved understanding may ultimately result in the development of new therapies for many diseases.

2 HISTORY

The foundation of molecular diagnosis is the establishment of DNA as the factor of inheritance, a concept introduced by Avery in 1944.[1] This was followed closely by the elegant elucidation of the structure of DNA by Watson and Crick[2] in 1953. The subsequent application of these discoveries for molecular diagnosis has been

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

made possible by the development of new methods for analysing nucleic acids.

One such technique was introduced in 1975 by Southern[3] and involved the transfer of DNA, following size separation by gel electrophoresis, onto a solid support followed by hybridization to a probe. This technique is now referred to as the Southern blot and has been used for many of the molecular analyses in the 1980s.[4] Many of the subsequently developed methods for RNA and protein analysis, namely the northern and western blots, also bear certain resemblance to the Southern blot. In 1977, two groups have successfully developed methods for sequencing DNA.[5,6] The basic sequencing concept has been modified in numerous ways, including the introduction of fluorescence-based DNA sequencing[7] which is important in pushing the throughput of sequencing efforts.

A key concept that was introduced in the late 1970s was the idea of human DNA polymorphism[8] which has led to the flurry of papers on linkage studies in the 1980s.[9,10] In 1976, the first demonstration of the use of molecular techniques for clinical diagnosis was achieved.[11]

Up to 1985, the performance of molecular analysis generally takes many days or even weeks, and before this type of analysis can have a major clinical impact the turnaround time has to be markedly shortened. An important technique that has been instrumental in bringing molecular analysis to the clinical laboratories is the polymerase chain reaction (PCR).[12,13] This technique has made it possible to provide an analytical result within hours and allows molecular analysis to be carried out with unprecedented sensitivity, even down to a single molecule level.[14] The latter development has been important in the development of new diagnostic modalities, such as the analysis of single biopsied cells from preimplantation embryos.[15]

Up to 1989, the mapping of the human genome and the linkage of specific chromosomal regions to particular diseases had been hampered by the relative paucity of suitable polymorphic markers. In 1989, it was discovered that simple tandem repeat sequences in the human genome could serve as highly informative and frequent polymorphisms.[16,17] This discovery has made possible the rapid advances in linkage studies in the 1990s and the introduction of new concepts of genetic pathologies such as triplet repeat expansion and microsatellite instability in cancers.

The availability of a complementary set of technologies has made possible the launch of the HGP in 1990. The results from this project are expected to have long-term ramifications for science and medicine in the 21st century.

3 SAMPLE PREPARATION

3.1 Sources of Materials

Multiple sources of patients' specimens can be used for molecular analysis in a clinical setting. These include peripheral blood, plasma, serum, bone marrow, tumors and tissue biopsies. To obtain high integrity nucleic acids, especially RNA, from the specimens, one needs to process the samples as soon as possible.[18] In general, DNA samples are less fragile and thus isolated cells and cell-free components may be stored at $-20\,^{\circ}C$ before DNA extraction.

3.2 DNA Preparation

One of the first steps in DNA extraction is cell lysis followed by proteinase digestion.[19] Nucleic acids are then separated from proteins using phenol–chloroform–isoamyl alcohol. To obtain high purity DNA, RNA can be removed by digestion with RNases.[19] After ethanol precipitation and washing in 70% ethanol, DNA is resuspended in water or a Tris-based buffer and subjected to quantity measurement and quality assessment before molecular analyses. Alternatively, the application of genomic columns containing anion-exchange resin that binds DNA may increase the yield and purity of DNA.[19]

3.3 RNA Preparation

A popular method for RNA extraction involves the performance of cell lysis in the presence of guanidinium thiocyanate (which inhibits RNase activities), followed by acid–phenol–chloroform extraction.[18] DNA can be removed by DNase I treatment.[19] Extracted RNA is then subject to quantity measurement and quality assessment before molecular analyses. Alternatively, the application of columns containing anion-exchange resin that binds RNA may increase the yield and purity of RNA.[19] Recently, methods for simultaneous extraction of RNA and DNA from specimens have been developed which can improve the cost-effectiveness and minimize the amount of specimen required for molecular studies.[20]

3.4 Nucleic Acid Isolation from Archival Specimens

A powerful feature of molecular analysis is the ability of this technology to analyze archival materials, thus opening up the possible use of valuable archives in many pathology departments. Bone marrow smears or cell smears on glass slides are well established sources of starting materials.[21] Paraffin-embedded specimens are another very valuable source of test materials. However, the integrity of RNA or DNA may be poor if the archival specimens have been

stored for years or if the fixation steps have resulted in over-crosslinking of the DNA to proteins.

4 TECHNIQUES FOR MOLECULAR ANALYSES

4.1 Polymerase Chain Reaction

The PCR is a primer-directed enzymatic amplification of DNA using a DNA polymerase.[12,13] The PCR can be regarded as a simplified in vitro version of DNA replication which normally operates inside cells. The main components of a PCR consist of: (1) a pair of oligonucleotides, typically between 18 and 30 bases each, which are called the primers; (2) a DNA polymerase which is typically thermostable so as to withstand the high temperatures of the denaturation step; (3) deoxynucleoside triphosphates which provide the raw materials for the synthesis of new DNA strands; and (4) ionic and other cofactors.

The PCR can be regarded as consisting of three steps: (1) thermal denaturation – during this step, the normally double-stranded DNA molecules are denatured into a single-stranded form by heating, typically 94 °C to 95 °C; (2) primer annealing – during this step, the temperature is lowered to typically 50 °C to 60 °C to allow the primers to anneal to target sequences, that is sequences which share an exact or almost exact DNA sequence as the primers; and (3) primer extension using a DNA polymerase – during this step, which typically occurs at 72 °C, the DNA polymerase is allowed to extend the primers by synthesizing new DNA strands. Each combination of these three steps is called a PCR cycle. By the repetition of this process, exponential amplification of the target DNA sequences will result. The temperature alterations are generally carried out using instruments called thermocyclers. Each synthesized DNA molecule is called a PCR product which possesses a length from the 5′-end of one primer to the 5′-end of the second primer. Most PCRs are designed to generate a product length between 100 bp and 400 bp, although very long target lengths have been achieved using special combinations of polymerases.[22–24] The amplification factor (F) is given by Equation (1):

$$F = x(1 + E)^n \quad (1)$$

where x is the starting number of target molecules, E is the amplification efficiency and n is the number of PCR cycles.

With the performance of an additional reverse transcription step, the PCR can also be applied to the amplification of RNA targets, a process known as reverse-transcription polymerase chain reaction (RTPCR).[25] The use of polymerases exhibiting both reverse transcriptase and DNA polymerase activities, such as the *Thermus thermophilus* (*Tth*) DNA polymerase,[26] has enabled the performance of single-tube RTPCR.[27,28]

The PCR is a very sensitive process, capable of detecting a single molecule of target sequence.[14,29,30] This characteristic makes the PCR very valuable for the detection of target sequences which are present at extremely low concentrations, for example, certain pathogens.

The exquisite sensitivity of the PCR is also the inherent weakness of the method, namely, the proneness of the method to generate false-positive results due to exogenous contamination.[31–33] The main culprit for contamination is the carryover of PCR products from previous amplification reactions. Another source of contamination is target nucleic acid species from samples possessing the targets to those in which the targets are not endogenously present. Obsessive care is necessary during the sample preparation and PCR set-up stages to reduce the chance of contamination. Separate areas should be dedicated to the pre- and post-PCR steps. Multiple negative controls should be used to monitor the occurrence of PCR contamination.[34] A number of methods have been devised to reduce the chance of PCR contamination.[35–37] These methods are generally based on the principles of selectively destroying any contaminating PCR products or by rendering them unamplifiable.

4.2 Other Amplification Methods

Since the introduction of the PCR, many researchers and commercial companies have proposed alternative schemes aimed at accomplishing some or all of the functions of the PCR. One such method is the ligase chain reaction (LCR) which utilizes the ligation of oligonucleotides hybridizing in an adjacent fashion onto the target, with oligonucleotide pairs synthesized towards both strands of the DNA.[38] Thus every ligation cycle will in principle double the number of ligation templates. Potential clinical diagnostic systems based on the LCR have been proposed.[39,40]

The PCR and LCR both require the use of thermal cycling. Amplification schemes allowing the performance of isothermal amplification have also been described. Two such methods are nucleic acid sequence-based amplification (NASBA)[41,42] and strand displacement amplification (SDA).[43–45] NASBA is based on the sequential performance of a number of enzyme-mediated reactions: reverse transcription of an RNA target molecule using a reverse transcriptase; and the enzymatic digestion of the RNA template and the synthesis of a DNA strand in its place.[41] The resulting double-stranded DNA molecule

is designed such that an RNA promoter is present at one end. This molecule can then serve as a template for the transcription of multiple copies of RNA molecules, each capable of initiating the same series of reactions. The principle of SDA is based on repeated cycles of primer extension reactions following enzyme-mediated nicks in a double-stranded target DNA molecule.[46] During polymerization, the downstream strand is displaced and the displaced strands can then serve as templates for further cycles of the nicking and strand displacement steps.

Amplification using the Q-beta replicase[47] is an amplification scheme based on the use of an RNA-dependent RNA polymerase derived from the bacteriophage Q-beta.[48] Q-beta replicase is capable of producing a complementary product strand of a template RNA in as little as 12 s.[48] As the product strands are also templates for the replicase, exponential accumulation of the target RNA molecules will result. A single target molecule can yield an easily detectable amount of product in a short 15-min reaction.

In addition to these schemes which involve the amplification of nucleic acids, detection methods have been developed which depend on signal amplification, rather than target amplification. One such approach is the branched DNA (bDNA) assay which achieves signal amplification by secondarily binding large numbers of enzymatic reporters to hybridized probes.[49–52] The bDNA system is a solid-phase sandwich hybridization assay incorporating multiple sets of oligonucleotide probes and several simultaneous hybridization steps. Five to nine target-specific probes serve as capture extenders binding to the target DNA or RNA onto the surface of a microtiter plate.[50] A second set of target-specific probes (18 to 39) is used as labeled extenders binding to the target nucleic acid. In the first-generation assays, the labeled extenders also provide binding sites for the bDNA amplifier molecules with 15 identical arms. Each of these arms can bind three alkaline phosphatase-labeled probes. In other words, up to 3000 enzyme-labeled probes can be hybridized to each target DNA/RNA copy. Bound labeled-probes are detectable by using a chemiluminescent substrate, dioxetane, and quantified by measuring the light emission.[50] The resulting signal is proportional to the concentration of the target nucleic acid. The quantity of the target in the test sample is then determined from a standard curve.

In the second- and third-generation bDNA systems, preamplifier molecules are used to enhance the number of labeled probes bound to the target, and to reduce the background signal.[53] The labeled extender probe sequences are designed to bind to adjacent regions of the target to allow efficient hybridization to the preamplifier molecules. Two kinds of preamplifier molecules are used which contain the same repeat sequence and differ only in the sequences hybridized to the target probes.[53] Each preamplifier has a site specific to the overhanging sequences (15–16 bases) of the target probe set 2. When the overhanging sequences of two target probes are adjacent, the melting temperature increases and hence stabilizes the binding of the preamplifiers. Each preamplifier can hold up to 8 bDNA amplifier molecules and a total of 360 alkaline phosphatase-labeled probes. As a result, each target DNA/RNA may bind up to 10 000 enzyme-conjugated probes.

4.3 Blotting and Hybridization Techniques

Blotting of nucleic acids onto nylon membranes and subsequent ultraviolet (UV) illumination will immobilize the test DNA/RNA, which can then be subjected to hybridization with target probes afterwards. For standard Southern and northern blot analyses, nucleic acids on agarose gels are blotted onto nylon membranes by capillary action or vacuum transfer.[19] Radioactive or nonradioactive hybridization is conducted afterwards using, for example, ^{32}P-labeled or digoxigenin-labeled copy DNA (cDNA) probes or oligonucleotide probes.[19,54] After washing, the blots are exposed to X-ray films. When a nonradioactive technique is applied, an enzyme-conjugated antireporter antibody is added onto the membrane, which is then subject to colorimetric or chemiluminescent detection.[19,54]

4.3.1 Northern Blot Analysis

Northern blot analysis is used for studying messenger RNA (mRNA) expression of specific target genes.[19] Total RNA from samples is separated using gel electrophoresis and then subjected to ethidium bromide staining. The integrity of ribosomal RNA (rRNA) bands reflects the mRNA integrity. Total RNA is blotted onto a nylon membrane and subjected to prehybridization for blocking nonspecific binding and then hybridization with a labeled probe.

4.3.2 Southern Blot Analysis

Southern blot analysis is useful for analysis of deletion, rearrangement and methylation of target genes.[19] Generally, genomic DNA is first digested with specific restriction enzymes. A wide variety of restriction enzymes can be used for different purposes. For example, methylation-sensitive restriction enzymes that only cleave unmethylated sites but will not cut methylated residues could be used for the methylation analysis[55] (see also section 5.1). DNA fragments are then separated by gel electrophoresis, subjected to ethidium bromide staining and blotted onto a nylon membrane. In addition, the

Southern blot can also be used for confirming the identity of PCR products.

4.3.3 In Situ Hybridization

In situ hybridization is a technique for analyzing target nucleic acids within cells fixed on glass slides. Probes can be labeled with either radioactive or increasingly nonradioactive labels (e.g. digoxigenin).[56] After sealing with a coverslip, the targets are denatured by heat and then hybridized with the labeled probe. After appropriate washing steps, the hybridized probes are visualized, for example either by autoradiography for radioactive probes or by using an enzyme-linked colorimetric detection system for nonradioactive probes.

An important group of nonisotopic labels are fluorescent reporters, in which case the technique is called fluorescence in situ hybridization (FISH). FISH is used for many different purposes, namely the analysis of structural and numerical chromosome aberrations, clonality studies and clinical diagnosis. FISH enables the identification of the presence and location of a specific DNA region within morphologically preserved chromosome preparations, fixed cells, and fresh-frozen and paraffin-embedded tissue sections.[57] Chromosomal translocations, deletions, amplifications and other rearrangements are detectable by FISH.[58] The sensitivity of FISH allows the detection down to 1–10 kb and hence the precise localization of genes on chromosomes. FISH can be applied to interphase nuclei using centromere-specific probes or chromosome arm-specific telomeric probes.[59,60] For standard probe preparation, in vitro amplification and labeling with fluorescent dyes are conducted. Telomeric probes are used to improve the sensitivity for detecting microdeletions or other cryptic rearrangements in the telomeric regions.[60] Specific long DNA probes are prepared by vector cloning and oligonucleotide primed in situ labeling, and the signals are detected by an enzyme-linked detection system.[61] For analysis of gene amplification, fluorogenic gene-specific probes together with fluorescent centromeric reference probes are used.[62] Greater than 10 signals per cell or tight clusters of signals in >5% of cells in the confined regions are classified as gene amplification (see also section 5.1).

The recently developed multi-color and ratio-mixing FISH techniques using dual-color and three-color probes are reliable for simultaneous analyses of different chromosomal aneuploidies.[60,61,63,64] The recent development of spectral karyotyping (SKY) has allowed the simultaneous visualization of all human chromosomes[65] and promises to provide much enhanced precision for molecular cytogenetic analysis.[66,67]

4.3.4 Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) is a molecular cytogenetic method based on the co-hybridization of fluorescent-labeled test genomic DNA and normal reference genomic DNA on normal metaphase chromosomes.[68] The relative deficiency or excess of a particular chromosomal region will be detected as a color shift. Standard DNA is labeled by nick translation. Archival DNA (small fragment size of 400–1000 bp) can be labeled using a universal linkage system.[69] CGH enables the identification of all unbalanced chromosome aberrations of the test DNA, such as DNA gains or losses on specific chromosomes. Test DNA samples may be derived from fixed, paraffin-embedded and fresh-frozen cells and tissues. Four-color CGH is based on conventional CGH with an additional cyanine-5 (Cy5)-labeled reference DNA as an internal standard in hybridization.[70] This internal reference standard can identify inconsistently hybridized chromosomal regions and standardize the dynamic range of hybridization.

Chromosome-specific CGH is a newly developed approach for detecting cytogenetic abnormalities.[71] This combines flow sorting of chromosomes, degenerate oligonucleotide primed polymerase chain reaction (DOPPCR) and a modified CGH technique for identifying the site and extent of intrachromosomal gains or losses. Chromosome-specific paint probes for aberrant chromosomes and their normal homologs are first labeled and cohybridized on normal metaphase chromosomes. The ratio of the relative intensities of hybridization signals is determined.

4.4 Detection of Unknown Mutations

Many of the recent developments in molecular genetics have centered around the discovery of disease-causing genes and the elucidation of disease-associated mutations. Tools for the detection of mutations have played a major part in many of these discoveries. DNA sequencing remains the ''gold standard'' in the detection of mutations. However, before high-throughput sequencing at costs acceptable to most laboratories become commonplace, there is still a need for mutation screening.

The ideal method for mutation detection would desirably be accurate, fast, inexpensive, able to provide detailed information regarding the nature and position of the mutation, nonlabor-intensive, automatable and avoid the use of harzardous reagents. None of the currently available methods fulfill all of these requirements. Nonetheless, each of the available methods has its own strength–weakness profile and should be selected according to budgetary allocation, workload and project nature of individual laboratories.

There are two major classes of mutation screening methods, namely those that depend on the conformation of DNA molecules and others which rely on the detection of mismatched bases. The conformation-based methods are based on the principle that DNA molecules of different sequence contexts will exhibit different electrophoretic mobilities under particular conditions. One group of conformation-based mutation screening procedures are based on the use of denaturing agents and include denaturing gradient gel electrophoresis (DGGE),[72,73] temperature gradient gel electrophoresis (TGGE)[74] and constant denaturant gel electrophoresis (CDGE).[75] These techniques utilize the principle that areas of single-stranded DNA within double-stranded segments greatly retard the electrophoretic mobility of DNA through acrylamide gels. Denaturation within a region of DNA is strongly dependent on the sequence of that region and even single base change can be detected using these techniques. For DGGE and CDGE the denaturing agents are chemical in nature (usually formamide and urea), while for TGGE heat is used. DGGE and TGGE use a gradient of increasingly denaturing conditions over the length of the gel. CDGE uses a single concentration of denaturant very close to that which separates the strands of the normal fragment. Methodological variants involving combinations of these methods have been described and reported to exhibit advantages of their constituent methods.[76]

A second group of conformation-based techniques is based on the electrophoresis of DNA molecules under nondenaturing conditions. Examples of such methods include heteroduplex analysis (HA)[77] and single-strand conformation polymorphism (SSCP) analysis.[78] HA is based on the principle that mismatched bases between a mutant and wild-type strand will result in a DNA heteroduplex which has reduced electrophoretic mobility on a polyacrylamide gel.[77] HA has the main advantage that the assay conditions do not have to be determined for each DNA fragment. Recently, high-throughput versions of HA have been developed using denaturing high-performance liquid chromatography (DHPLC), instead of time-consuming gel electrophoresis.[79,80] The major advantages of this development include the use of automated instrumentation, rapidity (approximately 6 min per sample) and the ability to analyze relatively long DNA fragments (up to 1.5 kb).[80]

SSCP is based on the principle that single-stranded DNA molecules of different sequences will take on different secondary conformations in a denaturing polyacrylamide gel and will thus exhibit different electrophoretic mobilities.[78] Even though the electrophoretic conditions for SSCP are carried out under nondenaturing conditions, the DNA fragments to be analyzed are first denatured by formamide and heat prior to loading on the gel. A number of electrophoretic parameters, for example electrophoretic temperature and the presence of glycerol, can be varied which will determine the number of mutations that can be detected. Using a single gel condition, approximately 70% of mutations can be detected. This figure can be increased to approximately 95% by the use of multiple electrophoretic conditions.[81–83] Following electrophoresis, the separated DNA conformers are detected by radioactivity,[78] silver staining[84] or fluorescence.[84–86]

The second class of mutation screening methods are techniques that utilize base mismatch recognition. These techniques generally exploit chemicals or proteins that act at or bind to sites of mismatched bases in DNA.[87] One of the earliest examples of this class of methods is chemical mismatch cleavage (CMC).[88,89] CMC employs hydroxylamine and osmium tetroxide to modify DNA at sites of base mismatch. The modified DNA is then cleaved with piperidine and the reaction products are separated by polyacrylamide gel electrophoresis. The location of the mutation can then be deduced from the sizes of the cleaved fragments. The major disadvantage of CMC is that harzardous chemicals are used and therefore the method is not suitable for use in a routine laboratory.

In addition to the use of chemicals to detect mismatched bases, it is also possible to utilize proteins or enzymes for this purpose. Examples include S1 and mung bean nucleases.[90] More recent methods have utilized bacteriophage enzymes known as resolvases, such as T4 endonuclease VII[91,92] and T7 endonuclease I,[91] for cleaving DNA heteroduplexes. This approach has been called enzyme mismatch cleavage (EMC)[93] or enzymatic mutation detection (EMD).[94]

4.5 Detection of Known Mutations

Following the elucidation of unknown mutations, it is sometimes desirable to develop detection methods to specifically detect a particular mutation, especially if the mutation in question is a common cause of a disorder in a particular population. As DNA amplification is almost invariably used in modern methods for detecting known mutations, these methods can be classified into two main groups, based on the role of the amplification step. In the first group, the function of the amplification step is merely to produce a large quantity of product for subsequent analysis. In the second group, the amplification and diagnostic steps are combined such that the amplification step becomes mutation-specific.

Restriction enzyme analysis of PCR products is one of the first methods for the detection of previously characterized mutations.[12] The main limitation of this method is that a particular mutation may not result in restriction site creation or deletion in any known restriction endonuclease. This limitation can be overcome

to a large extent by the introduction of artificial mismatches in the primers so as to create restriction sites which are affected by the mutation.[95–97] Another well-established approach is the performance of allele-specific oligonucleotide (ASO) hybridization on dot blots of the PCR products.[98] In situations where there are a large number of possible mutations affecting a single gene, it is possible to speed up the procedure by performing a reverse dot blot, where oligonucleotides specific for the different mutations are immobilized on a filter and then a labeled PCR product is hybridized to the probes "in reverse".[99] Newer variations of allele-specific hybridization include the inclusion of fluorescent probes against either mutant or wild-type PCR products during amplification, with different reporters being used for the mutant- and wild-type-specific probes.[100–102]

For the second group of techniques for detecting known mutations, that is, those that rely on allele-specific amplification, the most important method is allele-specific PCR,[103] also known as the Amplification Refractory Mutation System (ARMS).[104,105] This method is based on the fact that the *Thermus aquaticus* (*Taq*) DNA polymerase that is commonly used for PCR does not possess proofreading capability and that a primer with a 3′-end that is mismatched to the template will prime with very low efficiency.[103,104] Thus, allele-specific PCR systems can be designed such that the 3′-end of the primers possesses the same sequence as the mutant or wild-type variety of a particular sequence. It is also possible to achieve allele-specific amplification using the LCR.[40] Apart from using PCR primers that are allele-specific, it is also possible to introduce a blocking oligonucleotide with a 3′-terminal dideoxynucleotide between the two primers such that the amplification of either the mutant or the wild-type allele is blocked by hybridization of this oligonucleotide, a technique known as "blocker PCR".[106] Methods combining the principles of allele-specific PCR and blocker PCR have also been described.[107,108]

4.6 DNA Sequencing

Methods for DNA sequencing were first developed in 1977.[5,6] The method by Maxam and Gilbert[6] is based on the chemical cleavage of DNA at a specific nucleotide using chemical methods. The chemically treated DNA fragments are then electrophoresed and the sizes of the fragments are dependent on the positions of the respective nucleotides. The method by Sanger, on the other hand, relies on the interruption of in vitro DNA synthesis at specific bases of the DNA segment to be sequenced, using dideoxynucleotides.[5] At present, the method by Sanger is the predominant method that is being used by sequencing laboratories around the world.

With the continual requirement for increased sequencing throughput, semiautomated sequencing has been developed.[7] These methods generally depend on the automated detection of fluorescence-labeled DNA fragments. Most of these semiautomated methods have relied on the use of gel electrophoresis. To allow further automation, DNA sequencing based on capillary electrophoresis has been developed[109,110] and instruments with multiple capillaries allow extremely high throughput and are expected to speed up projects with large sequencing requirements, such as the HGP (see section 5.6).

New methods have also been developed for DNA sequencing, including chip-based DNA sequencing (see section 4.10) and methods based on mass spectrometry.[111] These methods are hopeful candidates for further allowing the widespread application of DNA sequencing in clinical diagnosis.

4.7 Quantitation of Nucleic Acids

One of the simplest methods for quantifying nucleic acids is by the use of spectrophotometry. The absorbances at 260 nm and 280 nm are taken and the ratios of these absorbances are taken as an indication of the purity of the nucleic acids.[19] In general, a ratio of approximately 1.8 is taken as a relatively pure preparation of DNA.

Fluorimetry is another method for quantifying nucleic acids. This approach generally requires the addition of nucleic acid-binding fluorescent dyes and measurement using a fluorimeter. Examples of proprietary dyes which can be used include Hoechst 33258 and 33342, and Molecular Probes PicoGreen™.

Specific fragments of DNA or mRNA can also be quantified using quantitative PCR or RTPCR.[112] This method can be performed in a competitive or a noncompetitive manner.[112] Conventional quantitative PCR is generally regarded as a relatively difficult technique to standardize and has a relatively narrow dynamic range. These shortcomings have recently been largely overcome with the introduction of real-time quantitative PCR.[113,114] In this approach continuous optical monitoring of the progress of a PCR is performed by coupling target amplification to the generation of a fluorescent reporter.[113,114] This method allows the online acquisition of quantitative results without any post-PCR processing, thus effectively reducing the risk of PCR product carryover contamination. The availability of this method has allowed the rapid development of quantitative detection methods for gene expression,[115,116] infectious agents[117,118] and gene dosage[119] (see section 4.8).

Variants of the basic real-time quantitative amplification method have been reported based on different amplification strategies[45] or different fluorescent signal generation schemes.[120]

4.8 Homogeneous Assays for Nucleic Acid Amplification and Detection

Nucleic acid amplification technologies such as the PCR are essential for many types of molecular analysis. The main disadvantage of these amplification-based methods is their sensitivity to carryover contamination of amplicons from previous reactions.[31,32] This important shortcoming has hindered the large-scale application of molecular analysis in the clinical laboratories. Recently this obstacle has largely been overcome with the development of a number of homogeneous assays for nucleic acid amplification and detection. The main strength of these methods is that no postamplification processing is necessary, thus avoiding the liberation of amplicons to the laboratory environment.

These homogeneous assays have all relied on the continuous optical monitoring of an amplification reaction in which product amplification is coupled to the liberation of a fluorescent reporter. The kinetics of fluorescence change is then processed by an online computer system and proprietary algorithms are available to rapidly output the data in either a qualitative or a quantitative format. Most of the available systems are based on the PCR[113,114,121,122] although other amplification formats such as SDA have also been converted into a real-time format.[45] A number of signal generation systems have been developed, including those based on the 5′-nuclease assay (or TaqMan™),[123] the BDProbe Tec™ET system[45] and molecular beacons.[120] The performance of real-time nucleic acid amplification and detection requires the use of specialized thermal cyclers with online fluorescence detection capability. A number of such instruments are available commercially including those that are built upon a conventional DNA thermocycler[113] as well as those that utilize rapid thermal cycling using capillaries.[120]

These homogeneous assays have been applied for nucleic acid target quantitation,[113,114,121] infectious agent detection[117,118,120] and allelic discrimination.[100] Their rapidity and robustness are likely to catalyze the introduction of molecular diagnosis by the clinical laboratory.

4.9 In Situ Detection of Nucleic Acids

The extraction of nucleic acids from the target tissues for molecular analysis has the disadvantage that it destroys information regarding the localization of the nucleic acid species with respect to particular cell types and the subcellular location. To preserve such information the performance of nucleic acid analysis in situ is necessary. One method is to carry out in situ hybridization (section 4.3.3). Another method is to perform in situ nucleic acid amplification such as in situ PCR.[124] In situ PCR is the performance of amplification within intact cells or tissue sections of specific gene sequences, or mRNA species, to levels detectable by in situ hybridization and/or immunocytochemistry. In situ PCR has been subdivided into: direct in situ PCR in which reporter labels are incorporated during amplification; and indirect in situ PCR in which in situ amplification is carried out first, followed by in situ hybridization.[125] It has been accepted by many investigators that the indirect approach offers much better specificity than the direct approach.[126] In situ PCR technology requires exhaustive optimization of various empirical variables including tissue fixation, protease digestion, amplification parameters such as the hot start maneuver, hybridization stringency, and the use of DNase digestion (for in situ RNA analysis).[127] Purpose-built thermal cyclers for in situ PCR are available from a number of companies.

Apart from in situ PCR, other molecular methods have also been described for the intracellular analysis of nucleic acids, including the isothermal self-sustained sequence replication (3SR)[128,129] and the oligonucleotide primed in situ DNA synthesis (PRINS).[130]

4.10 DNA Chip Technology

DNA chip assays are referred to as biochips, oligonucleotide array assays, and hybridization array assays. DNA chip assays are composed of a large collection of cDNAs or expressed sequence tags (ESTs) immobilized on glass (termed microarrays) or sets of synthetic oligonucleotides immobilized on silicon chips (termed probe arrays). Regardless of the array chosen, the assay relies on the hybridization of a population of labeled DNAs in solution to DNA sequences immobilized on the solid phase. On oligonucleotide microarrays, different oligonucleotides are arrayed at discrete locations (a few micrometers to several millimeters in size) on a silicon chip. Very large oligonucleotide arrays have been produced with as many as 65 536 sites (all possible 8-mers), and efforts to place even larger numbers of probes on a chip are underway. Affymetrix has created the GeneChip® technology based on high density DNA arrays containing DNA sequences as a method to analyze genetic information in the human genome.[131] Application-specific DNA probe arrays are designed for the rapid screening of gene expression within selected portions of the human genome (described in section 4.10.2). Along with this technology, Affymetrix has developed instrumentation and software for array hybridization, fluorescence detection, data acquisition, and data analysis. In addition to this much higher density of information, DNA chip assays have an advantage over gel-based assays because the nucleic acids are bound to a reusable solid support, allowing for improvements in automation and data analysis. The DNA chip technology

allows biomedical researchers to study entire genes and gather information about expression and gene mutation patterns.

4.10.1 Gene Expression

With DNA chip assays, RNA is extracted from the cells or tissues to be studied, and ''tagged'' cDNA is then made from mRNA in the extract. The product, tagged with fluorescent nucleotide analogs, is hybridized to the array, which is then washed to remove unhybridized material. Hybridized fluorescence-labeled products can be detected directly. To do this, the array is optically scanned or ''read'' by an inverted scanning fluorescence confocal microscope with a triple laser illumination system, which can assess differing red/green/yellow emissions. The resulting data are analyzed by powerful computer packages which integrate and formulate quantitative data generated from the vast number of potential hybridizations on a single chip. For example, one population of cDNAs derived from a cancer cell line can be fluorescence-labeled with a red tag, while a second population of cDNAs derived from a reference cell line can be labeled green. If both populations of cDNAs bind to the same target on a chip, a yellow signal is obtained. In this way, global gene expression can be compared in two populations. The method's great potential is that it allows the simultaneous comparison of the expression of many thousands of genes in a single experiment.[132]

4.10.2 Genotyping

DNA array analysis has also been widely used to detect genetic mutations and polymorphisms. Currently available applications for the oligonucleotide array chips include DNA sequencing and mutation detection, for example, β-*globin* gene mutations in β-thalassemia.[133] The Collins groups at the National Institutes of Health developed DNA arrays of 96 000 oligonucleotides to screen for 24 heterozygous mutations within exon 11 of the hereditary breast and ovarian cancer gene, that is, *BRCA1*.[134] A diagnostic DNA chip able to detect all mutations within the *BRCA1* gene will require 400 000 probes and is currently under investigation.[135] The p53 chip developed by Affymetrix includes over 400 mutations that have been found to be associated with tumors and has been marketed to determine individuals with increased cancer risk.

With the growing understanding of the importance of sequence variations, for example, single-nucleotide polymorphism (SNP), between individuals, large pharmaceutical companies have invested heavily in DNA chip technology. In a related application, the efficacy of therapeutic treatment with protease inhibitors for AIDS patients can be monitored with DNA chips designed to detect sequence variants in the human immunodeficiency virus type 1 (HIV-1)-clad B protease gene that confers protease resistance.[136] It is more cost-effective to use a chip to determine the genetic variant of HIV harbored by a patient before starting therapy, than to prescribe an inappropriate drug to an individual who will then fail to respond.

4.10.3 Sequencing by Hybridization

To detect a gene expressed at levels as low as one copy per cell, the company Hyseq has developed sequencing by hybridization technology.[132] This technology can identify target genes without prior sequence knowledge. A series of short, overlapping probes are hybridized and reconstructed by software to recreate the DNA sequence. An extension of this technology yields a universal sequencing chip that is a potentially powerful tool for both diagnostics and gene discovery.

4.10.4 Current Limitations of DNA Chip Technology

At present, there are publicly available, validated cDNA and EST sequences for only a proportion of expressed genes. Out of a total of 10 000 to 50 000 expressed genes in a given human cell, only 15 000 can be detected by DNA chips because the publicly available Unigene set contains only 15 000 cDNA clusters, each representing a unique human gene. Another limitation is that several cDNA libraries must be analyzed to assess the full complement of expressed genes.

Currently, the most advanced expression array systems are very expensive and, as a result, have only been available to large pharmaceutical companies or the laboratories in which the technologies are being developed. It is possible to reuse chips, but there is a theoretical loss of sensitivity with each successive hybridization. Until the cost per experiment falls, the number of experiments that can be performed and the number of replicates per experiment will be limited. With few replicates, complete confidence in the results will only be obtained in cases with large changes in mRNA levels. Thus, it is possible that some low-abundance mRNA species will not be identified by DNA chip assays.

In addition, software and database systems to design arrays and collect, analyze, and interpret data from gene expression studies are still in their infancy. Very large quantities of data have to be managed both before and after the experiment, because direct access is required to all sequences, annotations, and physical DNA resources for the genes of the organism studied.

5 MOLECULAR PATHOLOGY IN CLINICAL CHEMISTRY

5.1 Cancer

Cancer can essentially be regarded as a genetic disease. Five different types of genetic alterations have been described in cancer cells:

1. Subtle genetic alterations: these include small deletions, insertions and single base pair substitutions. Examples of these subtle genetic alterations include activating mutations for oncogenes[137] and inactivating mutations for tumor suppressor genes.[138]
2. Copy number changes in chromosomes: these include the somatic losses or gains of chromosomes. Some of these changes can be observed by conventional or molecular cytogenetic analysis. Apart from cytogenetic analysis, these changes can also be observed by the study of polymorphic markers on the paternally and maternally inherited chromosomes. The loss of one of these chromosomes results in a phenomenon referred to as loss of heterozygosity (LOH).[139]
3. Chromosomal translocations: these are best characterized in hemopoietic malignancies including leukemias and lymphomas.[140] In most instances, chromosomal translocation fuses sequences of a transcription factor or receptor tyrosine kinase gene to those of a normally unrelated gene, resulting in a chimeric protein with oncogenic properties.[141] Another scenario involves the re-positioning of transcriptional regulatory genes to the neighborhood of highly active promoter/enhancer elements, such as those associated with immunoglobulin genes. Our knowledge of chromosomal translocations in human solid tumors is less detailed than that for hemopoietic malignancies, although a number of nonrandom alterations have been documented.[142] Recently, detailed molecular characterization has been accomplished for several human sarcomas[143,144] and may become the paradigm for other human solid cancers.[145]
4. Gene amplifications: these represent an increase in the copy number of a small region (generally 1 to 2 megabases (Mb) or less) of a chromosome.[146] Gene amplifications are generally only observed in relatively advanced neoplasms. The ''amplicons'' contain one or more genes whose expression can provide the cell with enhanced proliferative potential, with a growth advantage compared with cells not possessing the change.
5. Exogenous sequences: these include tumor viruses, which contribute genes resulting in abnormal growth. Examples include human papillomavirus (HPV) in cervical cancers[147] and hepatitis B virus (HBV) in hepatocellular carcinomas.[148]

Apart from these genetic alterations, it has been increasingly recognized that epigenetic factors are also important in oncogenesis.[149] Epigenetic inheritance is a biochemical modification of the genome which is heritable by progeny cells, without involving a change in DNA sequence. DNA methylation is now known to be an important mechanism of epigenetic inheritance[149,150] and involves the methylation of the C-5 position of cytosine by a DNA methyltransferase. One methylation-dependent oncogenic pathway is the inactivation of tumor suppressor genes by methylation of CpG islands of the promoter region.[151–153] A second epigenetic oncogenic mechanism is the disruption of genomic imprinting, referred to as loss of imprinting (LOI).[154,155] Imprinting is a term used for describing the phenomenon of differential gene expression or nonexpression based on the parent-of-origin of a particular allele of a gene.

The elucidation of the numerous genetic and epigenetic changes that can lead to cancer has provided new tools for the detection and monitoring of cancers. An important advance is the ability of molecular methods to detect the presence of malignancy from clinical materials that can be obtained relatively noninvasively, such as blood. Thus, there is a lot of interest in the detection of circulating tumor cells in the blood of patients suffering from a variety of cancers, not just cancers of hemopoietic origin.[156] Molecular targets that have been detected include tumor-associated genetic alterations, such as oncogene mutations, thus involving the analysis of tumor-derived DNA. A second class of targets include mRNA from the tissue of origin of the malignant tumor, such as tyrosinase mRNA from melanoma[157] and α-fetoprotein transcripts in patients with hepatocellular carcinoma.[54] In addition to blood cells, cell-free blood plasma and serum have also been proposed as valuable materials for tumor detection (section 5.5). Apart from blood, other easily assessable sources of bodily materials have also been used for tumor detection, including sputum,[158,159] stools[160,161] and urine.[162–164] The availability of these new and relatively noninvasive modalities for cancer detection may allow the earlier diagnosis of many neoplasms, leading to a prompter intervention and hopefully an improved survival from these diseases.

5.2 Prenatal Diagnosis

The identification of the causative genes for many inherited diseases has opened up the possibility of prenatal diagnosis for these disorders. The development of molecular cytogenetics has also made possible the performance of rapid chromosome analysis. A source

of fetal materials is necessary for carrying out prenatal diagnosis using these techniques. Fetal materials are usually obtained by invasive sampling methods such as amniocentesis, chorionic villus sampling, fetal blood sampling and fetal biopsy. However, these methods are associated with a finite risk to the fetus and mother.

The development of molecular biology has allowed the development of new methods for prenatal diagnosis which do not carry such risks. Amongst these methods, there is a real hope that the isolation of fetal nucleated cells that have entered the maternal circulation during pregnancy may allow the realization of noninvasive prenatal diagnosis.[165] The first demonstration that fetal nucleated cells do indeed enter into maternal circulation using molecular techniques was achieved in 1989,[166] using the amplification of Y chromosomal sequences from DNA extracted from maternal peripheral blood cells. Since then numerous investigators have repeatedly confirmed these observations[167–170] and have developed many methods aimed at enriching these extremely rare components of the maternal blood. Thus far, the most promising approaches are based on the isolation of fetal nucleated red blood cells that have entered into the maternal blood, using the fluorescence activated cell sorter,[171] magnetic sorting[172] and newer methods such as charge flow separation.[173]

Apart from obvious diagnostic possibilities, the trafficking of nucleated cells between the mother and fetus has raised numerous research opportunities for understanding the fetomaternal relationship on a molecular level.[174] For example, it is now known that the fetomaternal transfer of nucleated cells is actually a two-way process, with maternal nucleated cells being found in the fetal circulation,[174–177] in addition to fetal cells in the maternal circulation mentioned above. Interestingly, recent evidence indicates that certain fetal cell populations can persist for extended periods (e.g. years) following parturition[178] and that this persistence may lead to the development of autoimmune diseases such as systemic sclerosis.[179,180]

5.3 Mitochondrial Diseases

Mitochondria are intracellular organelles specializing in the production of cellular energy in the form of adenosine triphosphate (ATP) by the process of oxidative phosphorylation (OXPHOS). Most cells contain hundreds of mitochondria. Mitochondria possess their own genome which is a circular DNA molecule of approximately 16 500 base pairs.[181] Mitochondrial DNA carries genes for 13 polypeptides, all involved in OXPHOS, 22 transfer RNA (tRNA) genes and genes for the 12S and 16S rRNA. Mitochondrial DNA is transmitted through the cytoplasm of the oocyte at fertilization and thus is maternally inherited.[182] In addition, as there are multiple copies of mitochondria, each containing multiple copies of mitochondrial DNA, a cell can contain a mixture of wild-type and mutant mitochondrial DNA, a condition known as heteroplasmy. The stochastic and quantitative nature of mitochondrial genetics implies that the inheritance and expression of heteroplasmic mutations are highly variable. An additional complexity of the genetics of mitochondrial disorders is that mutations in *nuclear* genes can also affect OXPHOS[183–185] or the stability of mitochondrial DNA.[186,187] In these circumstances, the disorder can be inherited in a Mendelian manner. These features highlight the great care that is needed in counseling families with mitochondrial disorders.

Over the last 10 years, molecular alterations in mitochondrial DNA have been associated with several human pathologies. The first mitochondrial diseases to be elucidated on the molecular level include Leber's hereditary optic neuropathy (LHON), a sudden-onset blindness resulting from a missense mutation of the mitochondrial DNA,[188] and a sporadically occurring group of neurological diseases called chronic progressive external ophthalmoplegia (CPEO) and the Kearns–Sayre Syndrome (KSS), resulting from mitochondrial DNA deletions.[189] Since these discoveries, over 50 pathogenic mitochondrial DNA base substitution mutations and hundreds of mitochondrial DNA rearrangements have been identified in many neurodegenerative diseases (summarized in the website MITOMAP, www.gen.emory.edu/mitomap.html).

Apart from the relatively rare diseases mentioned above, some authors have suggested that mitochondrial dysfunction may underlie common processes such as aging and malignancy. The potential relationship between mitochondrial dysfunction and aging is supported by reports of age-related declines in OXPHOS enzyme activities[190,191] in skeletal muscle, liver, and brain and the associated accumulation of somatic mitochondrial DNA alterations in these same postmitotic tissues.[192–195]

With regard to cancer, multiple somatic mitochondrial DNA mutations, including intragenic deletions, missense and chain-termination point mutations, and alterations of homopolymeric sequences have been reported.[196–198] In addition, alterations in mitochondrial copy numbers have been described in a number of malignancies.[199] The exact relationship between these mitochondrial DNA alterations and malignancy is unclear at present although possible mechanisms include alterations in cellular energy dynamics, mitochondrial oxidative stress and modulation of apoptosis.

The increasing spectrum of disorders related to mitochondrial dysfunction has stimulated interest in the

development of rapid methods for characterizing mitochondrial DNA alterations.[200–202]

5.4 Diabetes Mellitus

Diabetes mellitus affects approximately 5% of the general population, with inter-ethnic and inter-geographical variations. The majority of cases are accounted for by two different types of diabetes mellitus, type 1 and type 2, which account for approximately 10% and 90% of cases, respectively. These two types of diabetes mellitus have distinct etiologies. Type 1 is typically an autoimmune disease in which β-cell destruction is followed by absolute deficiency of insulin. Type 2 diabetes, on the other hand, is characterized by a deficiency of insulin action as a result of a combination of insulin resistance and β-cell dysfunction that is manifested as inadequate insulin secretion in the face of insulin resistance and hyperglycemia. Genetic factors play an important part in both type 1 and type 2 diabetes, with concordance rates among monozygotic twins of 25–50% and 50–95%, respectively.

The recent advances in molecular genetics have allowed us to define the genetic factors associated with diabetes mellitus in more detail. Two approaches have been used to identify genes that predispose to diabetes mellitus: first, by testing candidate genes via the comparison of the frequency of alleles of specific genes in diabetic and control populations (case-control or association studies); and second, by genome scanning to identify chromosomal loci associated with disease susceptibility.[203,204] As type 1 diabetes is an autoimmune disease, one of the first candidate genomic regions to be examined was the human leukocyte antigen (HLA) locus. This locus is now referred to as *IDDM1* and has been estimated to account for 35–40% of the inheritance of the disease.[203,205,206] Detailed molecular studies have identified particular alleles of class II HLA genes that confer susceptibility or protection for type 1 diabetes.[207] Apart from the HLA region, a second susceptibility locus that has been identified using the candidate gene approach is the insulin gene locus on chromosome 11 (referred to as *IDDM2*). Amongst the polymorphisms in this region is the variable number of tandem repeats in the 5′-flanking region of the insulin gene. It has been estimated that the *IDDM2* locus accounts for approximately 10% of the familial inheritance of type 1 diabetes.[203,205,206] Further susceptibility loci for type 1 diabetes have been identified by whole genome scans. Detailed characterization of these candidate loci is still in progress.

Type 2 diabetes is a genetically heterogenous disease, with mutations in a number of genes or combination of genes contributing to the disease phenotype. Further complexity in the study of the genetics of type 2 diabetes is that different combinations of genes may be responsible for the disease in different populations. In addition, environmental factors, many of which are still ill-defined, are important for the pathogenesis of type 2 diabetes. A further complication is that in many instances type 2 diabetes is a late-onset disease. Consequently, for many studied families, the parents, especially those who are affected by the disorder, may have succumbed to complications of diabetes and thus may not be available for study. Similarly, many of the younger members of the studied family, even if they have inherited the diabetogenic genes, may not be old enough to develop the disorder. Because of these difficulties, many investigators have focused on more easily defined but rarer groups of type 2 diabetes. One example is type 2 diabetes which is caused by alterations of the mitochondrial genome.[208] A second example is a form of diabetes called maturity-onset diabetes of the young (MODY). For genetic study, MODY has the advantage that it is monogenic, with an autosomal dominant mode of inheritance and has an early age of onset, typically before 25 years. Detailed molecular genetic studies have recently identified a number of MODY genes including the glucokinase gene (MODY2),[209] hepatocyte nuclear factor-4α (MODY1),[210] hepatocyte nuclear factor-1α (MODY3)[211] and the insulin promoter factor gene (MODY4).[212] It is expected that further MODY genes will be discovered as mutations in these four genes do not account for all cases of MODY. However, the elucidation of at least a proportion of the genetic lesions accounting for MODY does allow for family screening in some affected kindreds. This development may have implications for the prompt institution of preventive measures, such as exercise, diet, weight control, as well as early treatment of symptomatic individuals. Apart from these genetic alterations, rare mutations/polymorphisms of the insulin gene,[213] insulin receptor gene,[214] glucagon receptor gene,[215] amylin gene[216] and insulin receptor substrate 1 gene[217–219] have also been described, with variable effects on glucose homeostasis. The significance of these mutations to "common" late-onset type 2 diabetes, however, remains unclear. Similar to type 1 diabetes, whole genome scans have also been attempted for type 2 diabetes, with a susceptibility locus located on chromosome 2, referred to as *NIDDM1*.[220] The difficulty of this approach is increased by the fact that different genetic factors may be predominant in different populations and thus genomic regions showing positive association with diabetes in a particular population may not exhibit the same relationship in other populations.[221] It is expected that further data will be forthcoming over the next few years to allow a more precise definition of the molecular genetic factors involved in type 2 diabetes.

5.5 Molecular Analysis of Cell-free DNA in Plasma and Serum

It has been known for a number of years that cell-free DNA can be found in the plasma and serum of human subjects.[222,223] Of particular interest, the level of plasma DNA is elevated in individuals with cancer,[224] thromboembolism[225] and systemic lupus erythematosus.[226] Recent molecular characterization indicates that a proportion of the circulating DNA in cancer patients possesses tumor-associated genetic[227–230] or epigenetic[231,232] alterations or neoplasia-associated viral nucleic acids.[233] These data suggest that plasma DNA analysis may be a useful method for the non-invasive detection or monitoring of a number of cancers.

In addition to tumor-derived DNA, other types of cell-free DNA species have also been detected in the plasma/serum. Thus, cell-free fetal DNA has recently been found in the plasma of pregnant women.[234] This discovery has opened up a new approach for noninvasive prenatal diagnosis.[235,236] In addition, abnormal levels of circulating fetal DNA have been found in a number of pregnancy-associated disorders, including preeclampsia[237] and preterm labor.[238] In addition to fetal DNA, cell-free DNA derived from the graft has also been demonstrated in the plasma of liver and kidney transplant recipients.[239] It is likely that other types of circulating nucleic acids will be found in the circulation and that plasma- or serum-based molecular diagnostics will find an increasing number of potential clinical applications.

5.6 The Human Genome Project

The HGP was originally conceived in the mid-1980s as an ambitious effort to characterize the human genome, yielding ultimately the DNA sequence of the human genome, with a projected completion date of 2005. The project represents an enormous undertaking, with the human genome consisting of some 3 billion base pairs, in which coding sequences for 50 000 to 80 000 genes are distributed. At its inception, the HGP was expected to be a project costing some US$ 3 billion over a 15-year period. The project has now evolved into a collaborative effort with input from many countries.

The goals of the project, as initially conceived, were threefold: (1) the creation of genetic maps; (2) the generation of physical maps; and (3) the determination of the entire DNA sequence of the human genome. The first two goals can be regarded as preliminary characterizing efforts, paving the way for the third goal. The genetic and physical maps will provide a series of landmarks for directing sequencing efforts at particular genomic regions and, as of 1999, these first two goals have been completed.[240] Efforts are now focused on the third goal, with a ''working draft'' of the human sequence to be produced by the end of 2001, with a targeted completion date of the entire sequencing project to be 2003, 2 years ahead of the previous projections.[240] Additional goals have now been set, including the development of new sequencing technologies, the promotion of the new science of functional genomics, the studying of human genome sequence variation and the sequencing of other genomes. The potential usefulness of the latter goal has been illustrated by the completion of the genomic sequencing of *Caenorhabditis elegans*, the first completed genome sequence for a multicellular organism.[241]

Implicit in the HGP is the idea that an improved understanding of the human genome will be beneficial to our understanding of the fundamental workings of the human body in health and disease. These developments are likely to improve our ability to diagnose diseases more accurately and precisely and in some cases even before clinical signs of disease manifest themselves. For example, individuals known to possess genes that predispose to cancer or diabetes may be followed up intensively under special programs. Ultimately, it is hoped that these developments will change today's ''treatment-oriented'' health care to one that is more ''prevention-oriented'', by the stratification of individuals with respect to their genetic susceptibility to diseases.[242] The HGP may also catalyze the discovery of new genetic pathways which may be amenable to therapeutic intervention.

The HGP raises numerous ethical and social issues. It also generates concerns regarding the confidentiality of one's own genetic information, the proper institution of genetic counseling prior to DNA testing and potential problems regarding genetic discrimination either at work or by insurance companies. For these reasons, technical advances brought by the HGP should be accompanied by improvement in our understanding regarding the ethical, legal and social implications of these new data. In this regard programs such as the ''Ethical, Legal, and Social Implications'' (ELSI) working group have been set up to address these issues.

ACKNOWLEDGMENTS

ABBREVIATIONS AND ACRONYMS

ARMS	Amplification Refractory Mutation System
ASO	Allele-specific Oligonucleotide
ATP	Adenosine Triphosphate
bDNA	Branched DNA
CDGE	Constant Denaturant Gel Electrophoresis
cDNA	Copy DNA
CGH	Comparative Genomic Hybridization
CMC	Chemical Mismatch Cleavage
CPEO	Chronic Progressive External Ophthalmoplegia
DGGE	Denaturing Gradient Gel Electrophoresis
DHPLC	Denaturing High-performance Liquid Chromatography
DOPPCR	Degenerate Oligonucleotide Primed Polymerase Chain Reaction
ELSI	Ethical, Legal, and Social Implications
EMC	Enzyme Mismatch Cleavage
EMD	Enzymatic Mutation Detection
EST	Expressed Sequence Tag
FISH	Fluorescence In Situ Hybridization
HA	Heteroduplex Analysis
HBV	Hepatitis B Virus
HGP	Human Genome Project
HIV-1	Human Immunodeficiency Virus Type 1
HLA	Human Leukocyte Antigen
HPV	Human Papillomavirus
KSS	Kearns–Sayre Syndrome
LCR	Ligase Chain Reaction
LHON	Leber's Hereditary Optic Neuropathy
LOH	Loss of Heterozygosity
LOI	Loss of Imprinting
Mb	Megabases
MODY	Maturity-onset Diabetes of the Young
mRNA	Messenger RNA
NASBA	Nucleic Acid Sequence-based Amplification
OXPHOS	Oxidative Phosphorylation
PCR	Polymerase Chain Reaction
PRINS	Primed In Situ DNA Synthesis
rRNA	Ribosomal RNA
RTPCR	Reverse-transcription Polymerase Chain Reaction
SDA	Strand Displacement Amplification
SKY	Spectral Karyotyping
SNP	Single-nucleotide Polymorphism
SSCP	Single-strand Conformation Polymorphism
Taq	*Thermus aquaticus*
TGGE	Temperature Gradient Gel Electrophoresis
tRNA	Transfer RNA
Tth	*Thermus thermophilus*
UV	Ultraviolet
3SR	Self-sustained Sequence Replication

This article examines the role of nucleic acid analysis in clinical chemistry. It is a broad-based article and begins with the background knowledge which will be needed to appreciate the succeeding sections. In the Introduction, structure and function of nucleic acids, hybridization, probe labeling, hybridization protection, polymerase chain reaction (PCR) and sequencing are discussed. Major sections are devoted to microbiological analysis (with particular emphasis on bacteriology), genetic diseases and screening [discussions are provided for cystic fibrosis (CF), heriditary fructose intolerance (HFI) and hemochromatosis along with an introduction to the Human Genome Project and single nucleotide polymorphisms (SNP)], other areas of human medicine (oncology, colorectal cancer and Alzheimer's disease (AD) are considered) and the biosensor approach. A discussion of interesting current and future developments, not only in nucleic acid analysis, but also in gene therapy, concludes the article.

1 INTRODUCTION

1.1 Overview

In the past decade, nucleic acids, in particular DNA, have been widely utilized as diagnostic tools in clinical chemistry. In this article, we shall examine some of the theoretical aspects of the field and then describe various applications in areas such as detection of genetic diseases, diagnosis of infectious disease and aspects of human medicine and, finally, an introduction to progress in biosensor development will be considered.

1.2 Structure and Function of Nucleic Acids

Nucleic acids are high-molecular-weight biomolecular polymers which, upon hydrolysis, yield pyrimidine and purine bases, a sugar component and phosphoric acid.[1] There are two main types of nucleic acid, DNA and RNA. The pyrimidine bases are cytosine (found in RNA and DNA) and thymine (DNA) or uracil (RNA). Both nucleic acids contain two purine bases, adenine and guanine. Structures of these bases are shown in Figure 1.

The sugar in RNA is ribose whereas in DNA it is 2-deoxyribose, both occurring in the furanose form. A purine or pyrimidine linked to a sugar is termed a *nucleoside* while a molecule containing base, sugar and phosphate group is called a *nucleotide*.

1.2.1 Base Pairing[2]

Planar bases can associate in specific ways by means of hydrogen bonding. The adenine : thymine (A.T) base pair has two hydrogen bonds while the guanine : cytosine (G.C) base pair has three. This Watson–Crick base pairing shows that the sugar groups are both attached to the bases on the same side of the base pair (Figure 2a and b). The pairs of bases are flat and may be stacked one above the other so that the molecule is represented as

Figure 1 The four bases of nucleic acids.

Figure 2 Watson–Crick hydrogen bonding.

Figure 3 Hoogsteen hydrogen bonding.

a spiral staircase with the base pairs forming the treads. Stacked bases form a hydrophobic core.[1] On the other hand, Hoogsteen base pairing involves atoms N6 and N7 of adenine rather than N1 and N6 of Watson–Crick hydrogen bonding (Figure 3). There are also cases where a triple helix is formed by two pyrimidine strands and one purine strand and it is right-handed with an adenine-strand Watson–Crick hydrogen bonded to a thymine or uracil one and a third pyrimidine-strand Hoogsteen hydrogen bonded to the purine strand and parallel to it (Figure 4).[2]

1.2.2 Denaturation and Renaturation[1]

When double-stranded DNA (ds-DNA) molecules are subjected to extremes of temperature or pH, the hydrogen bonds are broken and the strands become separate. The DNA is denatured and changes from a double helix to

Figure 4 Triple helix formation. (a) Schematic view with third strand dotted. Base triplets [(b) TAT and (c) CH + GC] with extra pyrimidine bound by Hoogsteen hydrogen bonds in the major groove of the duplex.

a random coil (the helix–coil transition). If heat is the denaturant, the DNA is said to melt and the temperature at which the strands separate is termed the melting temperature, T_m. This transition is affected by the G + C content of the DNA, the nature of the solvent and nature of the DNA. There are three hydrogen bonds in G + C but only two in an A + T base pair, thereby making the G + C more stable and leading to a higher T_m. With regard to the solvent, at low concentration of counterion denaturation occurs at low temperature, whereas at high concentration T_m is increased.

Renaturation occurs when two DNA strands are reassociated to form a double helix. This process is dependent on the concentration of DNA molecules and the time allowed for reassociation. Renaturation is usually expressed as C_0t, where C_0 is the initial concentration in moles of nucleotide per liter and t is the time in seconds.

1.3 Hybridization

The employment of nucleic acid analysis primarily depends on the occurrence of hybridization, i.e. the formation of the Watson–Crick double helix from two single-stranded regions of DNA which are

complementary to each other.[3] The process was first reported in 1962[4] and success depends upon the two single strands having some degree of complementarity, the extent of which determines the stability of the ds-DNA which is formed. The stability increases when there is maximum hydrogen bonding and base stacking.[3]

RNA molecules can also take part in hybridization and base pairing can occur between complementary strands of DNA, between DNA and RNA and between complementary strands of RNA. A short (usually 15–30 base pairs but, in some cases, much longer) known segment of nucleic acid which is used to investigate an unknown sample for the presence of complementary sequences via hybridization is called a *nucleic acid probe*.[5]

1.3.1 Types of Probe[6]

Several types of probe are commonly encountered in clinical chemistry and these include cloned DNA probes which contain a known segment of DNA which is inserted into a plasmid vector. Cloned DNA probes are used to detect complementary species on Southern (DNA) or Northern (RNA) blots. These probes are usually >200 base pairs in length. Another common type is the synthetic DNA probe obtained either through oligonucleotide synthesis (by a commercially available DNA synthesizer) or by PCR amplification which allows large amounts of specific DNA probes to be obtained from small quantities of initial material.

RNA probes are usually obtained by the use of cloning vectors. These have found use in the detection of low concentrations of messenger RNA (mRNA).

1.3.2 Factors Affecting Hybridization

Many factors affect hybridization reactions, some of which are as follows:[7,8]

1. Temperature: at low temperature, the reassociation rate is determined by the difference in free energy between the unassociated and transition states. At higher temperature, the stability of the duplex is reduced until it is unstable and the hybrid melts.
2. Monovalent cation concentration: the T_m of a hybrid is reduced at low salt concentration because cations stabilize the DNA duplex.
3. Base composition especially with respect to G + C because rate of hybridization increases to some extent as this percentage increases. A higher G + C percentage also leads to an increase in T_m.
4. Duplex length: the rate of hybridization is proportional to the square root of the length of the smallest fragment.
5. Degree of mismatching of bases in the hybrid.
6. pH: hybridizations are normally performed in the pH range 6.8–7.4. Between pH 5 and 9, it is usually independent of pH.
7. Accelerators: inert polymers such as 10% dextran sulfate and 10% poly(ethene glycol) increase the rate of hybridization, probably by concentrating the probe and by increasing the extent of reaction.

1.3.3 Hybridizations on a Solid Support

This was first described in 1965[9] whereby a single-stranded DNA (ss-DNA) or RNA is immobilized on a solid support, e.g. nylon, nitrocellulose or polystyrene. This is useful for hybridization with the probe in a liquid phase[3] and there are several variations of solid support hybridization assays. We shall briefly consider dot/blot hybridization, Southern, Northern and Western blots and in situ hybridization.

1. Dot/blot hybridization: in this procedure, several samples are immobilized on the solid membrane. Manual addition of samples leads to a random shape (a blot) whereas with commercial devices the shape is regular (a dot).[5] This method allows all samples to be processed simultaneously with both samples and controls being treated under the same conditions.
2. Southern, Northern and Western blots: the Southern and Northern blots use restriction enzymes to cut DNA or mRNA which is obtained from tissues.[10] After digestion, the fragments are separated by electrophoresis, stained with ethidium bromide and the bands are observed under ultraviolet (UV) light. The DNA is then blotted on to a piece of electrostatically charged paper (a nitrocellulose membrane). Finally, hybridization is done using a labeled probe which binds to the fragment of interest with visualization by autoradiography.[10] The Northern blot is more difficult to perform because of the unstable nature of mRNA. The Western blot is used to analyze proteins by using antibodies which are specific for certain regions of the protein.
3. In situ hybridization: this is a special type of assay which uses intact cells, tissues or chromosomes and is used to demonstrate the presence of a particular gene within the material under study. The technique is more difficult than those previously described because the molecules have to reach the target in the tissue.[10] With chromosomal analysis, fluorescent detection is used whereby the technique is called fluorescent in situ hybridization (FISH). Since each

sample must be processed individually, the method is tedious and time-consuming.[3]

1.4 Probe Labeling

The type of labeling depends on the sensitivity of detection which is required for the particular analysis. For high sensitivity, it is common to use radiolabeling techniques even though there are problems with health hazards, storage and length of detection time.[6] Hence nonisotopic methods have become fairly popular.

1.4.1 Isotopic Labeling

The most common isotopes used are ^{32}P and ^{35}S but ^{33}P, ^{125}I, ^{14}C and ^{3}H have found use in several applications. ^{32}P has the highest emission energy and so will lead to the highest detection sensitivity. However, it has a short half-life ($t_{1/2}$) of 14.3 d, which limits its usefulness. If lower emission is required, it is wise to use either ^{35}S ($t_{1/2} = 87.4$ d) or ^{33}P ($t_{1/2} = 25.4$ d).[6] Methods of labeling DNA probes include nick translation,[11] which is used to label ds-DNA, and random priming,[12] where the template probe is denatured and then allowed to anneal with short oligonucleotides of random sequence.[5] It should be noted that, depending on which end of the probe is to be labeled, different enzymes are used. For 5′ labeling (e.g. with ^{32}P) it is common to use T4 polynucleotide kinase, whereas for the 3′ end, terminal deoxynucleotidyl transferase (TdT) is preferred.[5]

1.4.2 Nonisotopic Labeling

Most of the nonisotopic methods involve reactions with the chemical. Detection is usually by absorbance, fluorescent or luminescent systems or by pH electrodes or sensor technology (see section 5). Methods may be classified as either direct or indirect, with the former used for detection of standardized target biomolecules whereas the latter are used for biomolecules which are not specific. Direct methods require the reporter groups (e.g. fluorescein, rhodamine, alkaline phosphatase, horseradish peroxidase) to be directly coupled to the probes. In the indirect approach, however, there is also a noncovalent interaction between the probe and a molecule which binds to the probe. Examples of these include biotin, digoxigenin and immunogold.[13] Some of these probe detection systems are summarized in Figure 5.

1.4.3 Hybridization Protection Assay[14]

The hybridization protection assay (HPA) uses short, sequence-specific probes to detect nucleic acid targets of interest. In the most common format, an acridinium ester (AE) molecule is covalently attached to each probe molecule. The format is homogeneous, requires no

Figure 5 Probe detection systems.

Figure 6 HPA for the detection of mutations.

physical separation steps and can rapidly and sensitively detect all single-base mismatches, multiple mismatches, insertions, deletions and genetic translocations. The HPA method consists of three main steps (Figure 6): (i) the AE probe is added to the sample followed by hybridization; (ii) a mildly alkaline solution is added to hydrolyze AE linked to unhybridized probe; and (iii) detection of remaining AE as a measure of the amount of target present.

HPA is readily used to detect mutations such as a point mutation in the reverse transcriptase (RT) coding region of human immunodeficiency virus (HIV)-1, the F 508 mutation in CF and in cancer mutation (section 4). The technique has also been utilized in Food and Drug Administration (FDA)-approved kits for detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* (section 2.1.4)

Advantages of the HPA method include the combination of two separate approaches to discriminate matched and mismatched duplexes, rapidity, simplicity, simultaneous detection of multiple targets and detection requires only a luminometer. However, the method has a few drawbacks, the main one being that samples cannot be re-read since the ester reacts only once with alkaline peroxide to

produce light. Also, multiple analyte detection is actually limited to about five analytes.

1.5 The Polymerase Chain Reaction

The PCR is an in vitro technique which allows the amplification of a specific DNA region which lies between two regions of a known DNA sequence.[15] The method was invented by Kary Mullis,[16] who shared the Nobel Prize for Chemistry in 1993 for this work. The PCR involves three major steps: denaturation, annealing and polymerization (Figure 7).[17]

The template DNA (i.e. the DNA which will be amplified) is usually a ds-DNA fragment. However, for PCR to occur (because of the enzyme used, Taq polymerase derived from *Thermus aquaticus*), ss-DNA is required and so denaturation is carried out at 92–95 °C. The enzyme is stable at these high temperatures. Following denaturation, the mixture is quickly cooled to about 55 °C, where the base sequences anneal to the single strands of DNA and this process is followed by polymerization at about 72 °C (this is the optimum temperature for Taq polymerase). Here, the enzyme incorporates nucleotides into the DNA strand thus producing a complementary copy of the DNA template.[17] The entire cycle of denaturation, annealing and polymerization is repeated 20–30 times.

After each cycle, there is a doubling of the number of DNA molecules present and the final number of copies of target sequence is expressed by the formula[15] $(2^n - 2n)x$, where n = number of cycles, $2n$ = first product obtained after cycle 1 and second products obtained after cycle 2 with undefined length and x = number of copies of the original template. Thus, after about 20 cycles, a 10^6-fold increase in material is obtained.

Figure 7 The PCR.

The basic components of a PCR amplification include DNA template, DNA Taq polymerase, deoxynucleoside triphosphates (dNTPs), primers (short ss-DNA molecules which are complementary to the ends of a defined sequence of DNA template), buffer [usually a mixture of tris(hydroxymethyl)aminomethane (TRIS)–HCl, KCl, $MgCl_2$ and gelatin] and $MgCl_2$. These are covered by a thin film of mineral oil in the tube before placing into a thermal cycler. Mg^{2+} ions form a soluble complex with the dNTPs, which is necessary for dNTP incorporation. They also stimulate polymerase activity and increase the T_m of the ds-DNA.[15]

There are several critical parameters which need to be considered when performing PCR to ensure a positive outcome.[18] These include reagent purity, primer selection (especially length and complementarity to template), template purity and concentration, using only the required amounts of dNTPs as increasing the concentration does not lead to greater efficiency and optimization of the time required for each step of the thermal cycling process.

To determine if the reaction is successful, a gel electrophoresis experiment is performed with staining being effected by using ethidium bromide, a fluorescent dye which intercalates with the DNA. Visualization under UV light is done. Molecular weight markers are usually electrophoresed in adjacent cells to allow accurate size determination of the product.[15]

Contamination is a major concern when performing PCR. Sources of possible contaminants include biological samples such as hair and skin cells, sample collection methods, laboratory equipment, pipets and pipet tips, centrifuges and electrophoresis apparatus. To reduce the possibility of contamination occurring, several precautions can be taken.[17,19] These include a physical separation of pre- and post-PCR amplifications, micropipettors specifically devoted to PCR use, the use of positive displacement pipets or plugged pipet tips, aliquoting of reagents and negative controls performed for each experiment.

These considerations are of prime importance in the clinical laboratory where false-positive results can be devastating to both the patient and the credibility of the laboratory.

1.6 DNA Sequencing[20]

In many instances, the DNA sequence must be known so as to allow for further investigation. A rapid method is to do DNA sequencing followed by a computer-assisted search for restriction endonuclease cleavage sites. This is especially useful in obtaining structural information about cloned genes and their products and it also provides a detailed analysis of the 5′ and

3′ noncoding regulatory regions of a gene. Finally, DNA sequence information is essential for site-directed mutagenesis.

There are two main methods for DNA sequencing. (a) The dideoxy (Sanger) sequencing method[21] is an enzymatic system which was developed by Fred Sanger et al. and it uses a DNA polymerase to synthesize a complementary copy of an ss-DNA template. Chain elongation occurs at the 3′ end of a primer DNA which is annealed to template DNA. Overall chain growth is in the 5′ to 3′ direction. (b) The chemical sequencing (Maxam–Gilbert) method was developed by Maxam and Gilbert[22] and four sets of oligodeoxynucleotides are generated by placing a purified 3′ or 5′ end-labeled oligodeoxynucleotide in a base-specific chemical reagent which randomly cleaves DNA at one or two specific nucleotides.[20] In the first stage, bases are modified within the DNA molecule by using one of hydrazine, dimethyl sulfate or formic acid. Strand breakage is then brought about by adding piperidine to the nucleotides. This reaction cannot be allowed to go to completion because all possible cleavage products are needed in the complete mixture.

For both methods, electrophoretic methods such as slab gels and capillary electrophoresis (CE) are used to separate the reaction products and allow reading of the sequences.

2 MICROBIOLOGICAL ANALYSIS

In this section, we shall consider the increasing importance of nucleic acid analyses in bacteriology, virology and parasitology. Several examples will be discussed and references to further reading will be given along the way.

There are several advantages to the use of nucleic acid tests for diagnostic measurements. They can be used to confirm existing immunological tests; nucleic acids are usually stable to degradation; it is possible to amplify nucleic acids (e.g. by PCR), which is not the case with biological molecules such as proteins; and, finally, they are usually easy to develop and modify.[23] With specific reference to infectious pathogens, nucleic acid analyses also possess several advantages such as the potential to differentiate virulent and nonvirulent organisms based on genotype. Several examples will be encountered in succeeding sections. Also, the similarity between nucleic acid probes and related pathogens is very important in determining any genetic links of different pathogens.

It must be borne in mind that the technique is not perfect and several disadvantages may be encountered.[23] High background signals may be present and so it is difficult to detect weak positive samples. There are also cases where the additional sensitivity of nucleic acid tests may actually complicate the analysis of results when compared with culture methods, e.g. by identifying the pathogen or its components at concentrations which are epidemiologically unimportant.

2.1 Bacteriology

Many approaches have been utilized and many organisms have been detected by nucleic acid analysis. In this survey, brief introductions to some of the approaches are given.

2.1.1 Escherichia coli

Escherichia coli, and especially *E. coli* O157 : H7, has been widely studied. This species [which belongs to the group called verocytotoxigenic *Escherichia coli* (VTEC)] has been implicated in numerous outbreaks of food poisoning in the past decade, especially in the USA, Canada, the UK and Japan. The symptoms are particularly severe and include watery, followed by bloody, diarrhea, pus in stools and abdominal cramps. Eventually, conditions such as hemorrhagic colitis (HC) and hemolytic–uremic syndrome (HUS), both of which can lead to kidney failure and death, may result. Cattle are considered to be the major reservoir for O157 : H7, which is spread through fecal contamination of food.[24] Foods implicated in transmission have included ground beef, apple juice, potatoes, lettuce and cider.

Feng[25] has reported on the identification of O157 : H7 by using a DNA probe specific for an allele of the uid A gene. This was done by an oligonucleotide probe, PF-27, which contains a unique base substitution in the allele of the uid A gene. Using colony hybridization analysis of 239 bacteria, it was found that the probe reacted only with isolates of serotype O157 : H7. To verify probe specificity, DNA samples from various *E. coli* subspecies and O157 : H7 were digested with Hin f1 enzyme and examined by Southern blotting. The Southern analysis showed that PF-27 hybridized only with a fragment of about 700 base pairs in the O157 : H7 isolates. In a similar approach, Brunton et al.[26] used the *E. coli* attaching and effacing gene (eae) to detect O157 : H7 in cattle and humans. It was found that the majority of strains isolated from humans with bloody diarrhea and cattle with severe diarrhea were eae positive. In this paper, specific primers used to detect the eae sequences are described and it was suggested that a study of eae gene distribution is a useful method of distinguishing VTEC from other subtypes.

Several examples of the use of the PCR for detecting O157 : H7 have been reported. A group of workers at the FDA[27] have used PCR to detect low levels of the

bacterium in bovine feces. To improve the utility of PCR for this research, several enrichment culture procedures were carried out. It was determined that best results were obtained with boiling for 10 min when compared with enzyme digestion and phenol–chloroform extraction. Upon cooling to room temperature, RNase was added and this extract was used for PCR which involved amplification of primer sequences to detect the 614 base-pair fragment of the shiga-like toxin 1 (slt-1) gene. The authors suggested that boiling may destroy some PCR-inhibiting factor not removed by other procedures. By combining the boiling method with immunomagnetic separation (IMS), O157 : H7 was detected in about 8 h with a sensitivity of about 10^3 cfu g^{-1} feces.

Researchers at the United States Department of Agriculture (USDA)[28] used a multiplex PCR method to detect O157 : H7. In this case, a portion of the 60-MDa plasmid found in O157 : H7 was sequenced and a multiplex PCR was designed by employing primers specific for the eae A gene, conserved sequences of slt-1, slt-2 and the 60-MDa plasmid. This approach allowed the virulence genes (slt-1, slt-2 and eae A) and 60-MDa plasmid sequences to be targeted simultaneously. Thus, specific detection of O157 : H7 was obtained.

2.1.2 *Campylobacter spp.*

Campylobacters are a leading cause of enterocolitis in many developed countries and they have also been associated with bacteremia, reactive arthritis and meningitis.[29] Common sources of infection are unpasteurized milk, contaminated water and undercooked meats. Most infections are thought to be caused by *C. jejuni* and *C. coli*.[30]

Vanniasinkam et al.[31] recently reported a PCR method to detect *Campylobacter* spp. in clinical specimens. The PCR was based on the amplification of the 16S ribosomal RNA (rRNA) gene to detect the organism in human feces. The authors indicated that PCR detected twice as many positives as culture methods and it was proposed that by using rapid DNA extraction methods, PCR could be used as a routine diagnostic test for *Campylobacter*. PCR-based assays using 16S rRNA genes have also been developed for *Helicobacter pylori*,[32] the organism implicated as the causative agent in stomach ulcers.

Recently, it was discovered that surface antigens are important components required for the differentiating ability of serological tests and host recognition. With this in mind, Connerton and Connerton[33] have identified a gene encoding a membrane protein for *C. jejuni*. This was achieved following an immunoscreen of a lambda ZAP II genomic DNA library with antiserum raised against glycine-extractable proteins. Therefore, by using a molecular approach, the antigenic proteins from *C. jejuni* released after acid extraction were identified.

2.1.3 *Salmonella*

Salmonella is a Gram-negative bacterium which invades the mucous membrane and is spread by fecal–oral transmission. There are more than 2200 different *Salmonella* serotypes and most of these are human pathogens.[34] Typhoid fever caused by *S. typhi* leads to 16.6 million cases and 600 000 deaths annually, with the vast majority in Southeast Asia, Africa and South America.[35] *Salmonella* is the most important pathogen reported from foodborne illness in France with *S. enterica* being transmitted to humans by consumption of contaminated eggs and poultry products.[36]

PCR has been widely used as a diagnostic tool in detecting various *Salmonella* serotypes, mainly because it tends to overcome the difficulties encountered with culturing and enumerating these organisms from complex microbial communities. In one case, a primer set of oligonucleotides from the inv A gene has been evaluated.[37] Apart from being specific for *Salmonella* species, it was found that, after PCR amplification, it was possible to identify *S. typhimurium* by restriction enzyme analysis. It was suggested that this polymerase chain reaction/restriction enzyme (PCR/RE) method may be useful as a diagnostic tool for food analysis. In another case, a multiplex PCR with three sets of primers was developed for the detection of all serotypes of *S. enterica* and for the identification of *S. enteritidis* and *S. typhimurium*.[36] The authors found that a combined, modified semi-solid Rappaport Vassiliadis (MSRV) agar (Merck)/PCR method gave similar results to those of bacteriological methods and detection was possible in 2 d.

One interesting application for the differentiation of *S. typhi* and other species involves the use of a random amplified polymorphic DNA (RAPD) fingerprinting method.[35] Five primers were involved and it was concluded that the DNA of various strains of *Salmonella* could be discriminated in a few hours.

2.1.4 *Neisseria gonorrhoeae*

Gonorrhoea is one of the most important sexually transmitted diseases worldwide, with 720 000 cases in the USA in 1988.[38] Gynecological infections may cause infertility, chronic pelvic pain and ectopic pregnancy. There have also been reports of obstetric complications, neonatal pneumonia and conjunctivitis.

Over the past decade, DNA probe arrays have been developed for the detection of *Neisseria gonorrhoeae*, one of which makes use of a 2-h nonisotopic assay for direct detection in urogenital specimens.[37] This is the Gen-Probe test (PACE 2 from Gen-Probe Inc., San

Diego, CA, USA). It was found that with some slight modifications of the manufacturer's specifications, the DNA probe test was essentially equivalent to the culture method with respect to sensitivity and specificity. The test was found to be especially suitable for screening women for gonorrhoeal genital infections. The PACE 2 assay uses a chemiluminescent AE-labeled DNA probe which is specific for the rRNA of *N. gonorrhoeae*.[39] A urogenital swab specimen is placed in the PACE 2 transport medium whereby cells are immediately lysed thereby releasing their rRNA. The target rRNA is then hybridized to a labeled DNA probe and the extent of hybridization is measured in a luminometer.[39] Overall, the PACE 2 system is adequate for detection but it is unable to determine antibiotic resistance of positive specimens.

It has been reported recently that a micromachined chemical amplifier was successfully used to perform the PCR in continuous flow at high speed.[40] Input and output of DNA are continuous and amplification is independent of input concentration. A 20-cycle PCR amplification of a 176 base-pair fragment from the DNA gyrase gene of *N. gonorrhoeae* was performed in less than 20 min.

2.1.5 Mycobacterium tuberculosis

Tuberculosis (TB) is caused by members of the *Mycobacterium tuberculosis* complex and results in three million deaths a year worldwide. *M. tuberculosis* is transmitted from person to person via the airborne route. It is spread on droplet nuclei 1–5 μm in diameter which remain suspended in the air for long periods.[41] The HIV epidemic has led to an increase in the number of cases of TB, which causes bronchopneumonia, fibrosis and calcification. Other symptoms may include fever, night sweats, weight loss, anorexia, cough and blood in sputum.

A recent paper has reported on the identification and rifampin resistance testing of *Mycobacterium* species using high-density DNA probe arrays.[42] The array is based on two sequence databases: one for identification of mycobacteria (using 16S rRNA sequences) and the other for detecting rifampin resistance by targeting rpo B alleles. Species identification and rifampin resistance were determined by hybridizing fluorescently labeled, amplified genetic material generated from bacterial colonies to the array. This approach allows a number of genetic tests to be performed simultaneously but requires labeling of each sample to be tested.

It is also possible to detect and identify *M. tuberculosis* directly from sputum sediments by amplification of rRNA.[43] The results were available in 5 h (culture methods require about 6 weeks). This Gen-Probe Amplified *Mycobacterium tuberculosis* Direct Test™ uses enzymatic amplification of *M. tuberculosis* complex rRNA followed by detection of the amplicon (PCR product) with an AE-labeled DNA probe. The PCR assay involved amplification of insertion sequence IS 6110.

An integrated DNA analysis device has been used to measure nanolitre amounts of solutions containing DNA.[44] It amplifies the DNA and then separates and detects the products. This is done on a microchip 47 mm long, 5 mm wide and 1 mm high. The device requires a blue laser diode, an air pressure source and a programmable control unit. The fluids move around in microcapillaries and extra channels, valves and mixing chambers are needed for adding buffers, oligonucleotides, primers, DNA polymerase and fluorescent dyes. Amplification, purification and detection of a 106 base-pair fragment of *M. tuberculosis* required 1 h.

2.1.6 Bacterial Meningitis

Bacterial meningitis is a serious infection which needs rapid diagnosis and treatment, otherwise brain damage may occur. An evaluation of an extended diagnostic PCR assay for meningitis in cerebrospinal fluid (CSF) was performed using PCR.[45] Organisms evaluated were *Neisseria meningitidis*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Streptococcus agalactiae* and *Listeria monocytogenes*. A general bacterial amplicon from the 16S rRNA gene was obtained in a first step followed by species-specific regions. It was reported that the detection level was 4 fg of DNA per reaction, which corresponds to about one bacterial genome per reaction tube. This assay is able to detect bacteria in cultured suspensions as well as in clinical CSF samples.

2.1.7 Commercial Developments

Rapid pathogen detection using a microchip PCR array instrument has been reported.[46] The instrument is called the Advanced Nucleic Acid Analyzer® and uses 10 silicon reaction chambers with thin-film resistive heaters and solid-state optics. Features of the system include efficient heating and real-time monitoring, low power requirements and no moving parts. With this instrument, it is possible to analyze pathogens such as *Bacillus subtilis* and *Erwinia herbicola* vegetative cells.

2.2 Virology

The determination of the virus template sequence is enhanced by the genetic simplicity of viruses.[23] It is also of importance that the viral genes are well defined. In general, a conserved gene from a given virus pathogen is selected as a probe region because it should have the ability to detect various strains of the pathogen. In this brief account, the detection of viruses for hepatitis B and

C and for Epstein–Barr virus (EBV) infection will be discussed.

2.2.1 *Hepatitis C*

Hepatitis C virus (HCV) is an RNA virus which has been identified as the agent responsible for transfusion-associated and community-acquired non-A, non-B hepatitis.[47] It causes persistent infection in more than 90% of infected people and up to 70% of these will develop progressive liver disease over a 20–30-year period. An estimated 3.9 million Americans are currently infected with HCV.[48]

A rapid and reproducible method for assessment of the HCV load in serum has been reported.[47] This combines Taqman® technology (Roche) and the ABI Prism 7700™ (Perkin-Elmer) real-time sequence detection system. A reverse transcription PCR (this involves amplification of RNA by PCR by annealing a primer to the RNA template and then synthesizing a cDNA copy using RT, followed by PCR) which contains a dual-labeled fluorogenic probe to quantify the 5′ noncoding region of HCV was utilized. The probe contains a fluorescent reporter at the 5′ end and a fluorescent quencher at the 3′ end. When combined with the 5′–3′ nuclease activity of Taq polymerase, direct quantification of the PCR product is achieved. The authors concluded that the high sensitivity and reproducibility of real-time HCV RNA quantification allows the screening of a large number of samples, which makes it suitable for monitoring viral load during therapy. In a related method, Stapleton et al.[48] performed a comparison of HCV RNA detection in whole blood and plasma from 50 patients with chronic liver disease. The blood and plasma aliquots were independently tested for HCV RNA by RT PCR and it was found that whole-blood HCV RNA detection is more sensitive than commercially available tests.

2.2.2 *Hepatitis B*

Hepatitis B virus (HBV) is one of the causative agents of viral hepatitis, with an estimated 350 million people worldwide being chronic carriers and 100 million in China alone.[49] About 5–10% of carriers may be chronically infected and, of these, 25–40% may develop cirrhosis or liver cancer. HBV is a partially ds-DNA virus composed of a 42-nm outer shell and a 27-nm inner shell. A nucleic acid photo-cross-linking approach was used to develop a direct assay to quantify HBV DNA levels in serum. Cross-linker-modified DNA probes complementary to the viral genomes of the major HBV subtypes were synthesized and assayed in less than 6 h. It has also been reported that Naxcor (Menlo Park, CA, USA) have developed diagnostic tests for the detection of DNA and RNA targets based on the use of photo-cross-linked DNA probes.[50] It has been proposed[49] that cross-linking of DNA probes has certain advantages over conventional hybridization-type assays. These include the maximum amount of target will be captured and retained throughout the assay, leading to increased signal, and cross-linking allows the use of stringent wash conditions for effective removal of nonspecific background signals.

2.2.3 *Epstein–Barr Virus*

EBV causes infectious mononucleosis and EBV-related malignancies such as Burkitt's lymphoma and nasopharyngeal carcinoma. In immunocompromised individuals, such as acquired immune deficiency syndrome (AIDS) or transplant patients, EBV may cause B-cell lymphoma.[51] A real-time PCR assay was used to quantify the amount of EBV DNA in blood and it was indicated that $2–10^7$ or more copies of EBV DNA could be detected. By using real-time laser scanning coupled with a fluorogenic probe,[52] large numbers of amplified products were rapidly and accurately quantified.

2.3 Parasitology

Nucleic acid-based tests have also been applied to the detection of parasites. In this subsection we shall confine our attention mainly to *Plasmodium*, the agent responsible for malaria. More than 1.6 billion people live in malaria-endemic areas and imported malaria (via traveling) is fairly common. In 1991, there were 2332 cases reported in the UK with 1268 due to *Plasmodium falciparum*.[53] Malaria may cause fever, anemia, jaundice and splenomegaly along with renal failure.

Two PCR-based methods for diagnosing *Plasmodium falciparum* have been reported. One involves a nonradioactive system to detect the four species of parasite causing malaria.[54] Plasmodium-specific primers corresponding to the small-subunit rRNA genes of the parasite were used and a 291 base-pair fragment was amplified. It was possible to detect one parasite in 50 μL of whole blood. The second is an evaluation of a colorimetric assay to detect malaria in travelers.[55] A nonisotopic colorimetric PCR-based assay (Digene SHARP Signal System™) based on hybridization of a single-stranded RNA (ss-RNA) probe to denatured biotinylated PCR products and capture of the RNA–DNA hybrids on a streptavidin-coated microliter plate was developed. By using nested PCR (here, the larger fragment produced by the first round of PCR is used as the template for the second PCR) as the reference standard, it was determined that the colorimetric assay had a sensitivity of 100% and a specificity of 95.4%.

It should be noted that diagnostic tests have been, or are being, developed for visceral leishmaniasis

(caused by *Leishmania donovani*) based on cDNA probes.[56]

3 GENETIC DISEASES AND SCREENING

3.1 The Genetic Basis of Disease

Alterations in the genetic code (genetic defects) may be inherited or acquired. The former may involve a defect in a single gene or in many genes whereas the latter usually involve several genes.[57] These mutations may arise from injury by intrinsic or extrinsic agents. Since the development of nucleic acid probes, it has become much easier to detect alterations in genes. Alterations in the amount of chromosomal DNA may lead to developmental defects such as mental retardation.

One group of autosomal disorders is termed recessive. In these cases, the parents of affected individuals are not themselves affected but are carriers of the disease. This recessive disorder arises by inheriting two copies (one from each parent) of a defective gene. The most common autosomal recessive disorder is CF (see section 3.3.1), which occurs in Caucasian populations with a frequency of about 1 in 2500.[57] Other autosomal disorders are termed ''inborn errors of metabolism'', i.e. they involve a metabolic defect arising from deficiencies of a necessary enzyme.[56] Examples of this category include lipid storage disorders (e.g. Tay–Sachs disease), phenylketonuria (PKU) and abnormalities such as thalassemia, sickle-cell disease and hemophilia.

3.2 The Human Genome Project

It has been estimated that there are over 100 000 human genes (3 billion bases are involved in this genome).[58] As several diseases arise from genetic susceptibility, a map of the genes and their functions will assist in understanding diseases such as cancer, coronary heart disease and the genetic defects mentioned in section 3.1. The purpose of the Human Genome Project is to create a complete map and sequence of the human genome and work is being carried out in several major centers.[57] The task is enormous but it has already led to information on Huntington's disease, CF, breast cancer and AD. In March 1999, it was announced that the Human Genome Project will have its foundations completed by February 2000.[58] At that time, the working draft will be made publicly available. This effort is being undertaken by the Sanger Centre in Cambridge, UK, and laboratories funded by the National Human Genome Research Institute (NHGRI) in the USA, along with several other centers around the world. The final, high-quality sequence is expected to be completed by 2003.

3.3 A Survey of Some Genetic Diseases

3.3.1 Cystic Fibrosis

CF is an inherited disorder characterized by an abnormality of mucus production. The mucus is viscous and tends to clog bronchioles and pancreatic ducts, causing infection, inflammation and tissue damage. Eventually, death due to respiratory failure results.[59]

CF arises when there is a mutation in a gene on chromosome 7. This gene codes for the CF transmembrane conductance regulator which acts as a chloride channel. Thus, in epithelial cells there is impermeability to Cl^- ions which results in reduced production of Na^+ ions and water. Thus, the mucus becomes viscous and sweat is very salty.[59]

The gene for CF has been cloned and the most common mutant among whites is F 508.[60] Antenatal screening is carried out if a risk is known to exist, e.g. if a sibling has the disease. The test is usually performed at 10 weeks. By screening for F 508 and about five of the other most common mutations, about 85% of the cases can be identified.[58] Usually, screening for the F 508 allele makes use of PCR amplification followed by polyacrylamide gel electrophoresis (PAGE) to separate homo- and heteroduplexes (HD).[61] This test is now being combined with in vitro fertilization whereby the individual fertilized cells are screened for CF, affected embryos are discarded and normal embryos are used for implantation.

At present, research is being carried out with the aim of using gene therapy (i.e. inserting a normal working gene into cells containing a defective gene) to assist in providing treatment for CF and other genetic diseases. However, there are many problems, e.g. the gene and associated regulatory DNA must be isolated, sufficient DNA for treatment must be available, the gene has to be delivered to the nucleus of the cell and incorporation of the gene should not produce undesirable effects.[59]

3.3.2 Heriditary Fructose Intolerance

HFI is a genetic disorder resulting from mutation in the aldolase B gene which encodes the isozyme of fructose 1,6-biphosphate aldolase found in the liver, kidney and small intestine.[62] With this disorder, newborns and infants are intolerant of fructose in foods and this condition may lead to hypoglycemia, growth retardation and death. Standard methods of diagnosis are measurement of clinical symptoms upon intravenous fructose introduction and direct assay of aldolase activity in liver biopsy samples.[62] For newborns, the diagnosis is crucial, and rapid, noninvasive tests are required.

Research workers at Boston University[62] have amplified (by PCR) a region of genomic DNA from lymphocytes and prepared a biotin-tagged probe which is

hybridized to complementary poly(dT)-tailed allele-specific oligonucleotides (ASOs). The ASOs are bound to a nylon membrane and detection was by chemiluminescence. It was determined that the assay was able to detect two mutations which cause >70% of HFI worldwide. By using a reverse dot/blot methodology, it is believed that screening newborns is more easily achieved and simultaneous testing for several mutations can be carried out.

3.3.3 Hemochromatosis[63]

Hemochromatosis is an autosomal recessive disorder of iron metabolism which occurs in 0.2–0.5% of Caucasians. The disease leads to excessive accumulation of dietary iron, which may cause cirrhosis, cardiac failure, diabetes, arthritis and hepatocellular carcinoma. To prevent such serious conditions arising, it is vital to have early detection and treatment.

Recently, the HFE gene was identified as being responsible for hemochromatosis and so early genetic diagnosis is now possible, especially as two mutations have been detected in the gene. A multiplex PCR method has been developed which allows both mutations to be simultaneously detected. DNA was extracted from the blood of patients and PCR-mediated site-directed mutagenesis was used to create unique restriction sites in each product of a duplex PCR.

3.3.4 Phenylketonuria

PKU is also an autosomal recessive disorder which, if left untreated, may lead to mental retardation. In the USA, the incidence is from 1 in 10 000 to 1 in 25 000.[61] Phenylketonuriacs do not metabolize phenylalanine, which is an amino acid found in some foods. PKU arises as a result of a large number of mutations and, at present, no DNA analyses are available. This area is expected to become an important research activity.

3.4 Single Nucleotide Polymorphism

In April 1999, it was announced that an innovative collaboration between 10 pharmaceutical companies, the Wellcome Trust and leading academic centers will allow for the identification and analysis of the genetic markers known as SNPs, pronounced ''snips''.[64] The map will be used to identify specific genes involved in diseases, developing novel diagnostic tests and creating new ''personalized'' medicines based on an understanding of small genetic variations.

SNPs are common variations which occur in human DNA and scientists believe that these can assist in determining who will develop diseases such as cancer, AD, diabetes, arthritis and depression.[64] The map will allow answers to be obtained about the genetic factors responsible for causing disease.

4 OTHER AREAS OF HUMAN MEDICINE

4.1 Introduction

DNA probes are finding importance in various areas of human medicine as they are able to identify specific biological molecules associated with pathological conditions.[65] Some aspects of human medicine have already been covered in sections 2 and 3. In this section, special attention will be paid to just two areas: oncology and AD. Readers who require more detailed surveys are referred to Versalovic and Lupski.[65]

4.2 Oncology

Molecular probes can be used to diagnose tumors and to establish cell lineages and also to permit tumor grading.[65] It has also been established that nucleic acid probes may be used with biopsy material for in situ hybridization procedures to obtain more data from a specimen. It is also possible to combine DNA amplification methods with cytology to obtain specific diagnoses.[65]

4.2.1 Breast Cancer

In some countries, it has been estimated that up to 10% of the women may be affected by breast cancer, the strongest risk factor being family history.[66] In the UK, about 25 000 new cases are diagnosed each year and about 15 000 of these women will die. The genetic alterations responsible for breast cancer usually involve one of two genes, BRCA 1 and BRCA 2. The former was isolated in 1994 and since then more than 300 disruptive mutations have been identified in breast and ovarian cancer.[67] In Australia, it has been reported that the proportion of women with breast cancer before age 40 who carry a germline mutation in BRCA 1 was estimated at 3.8%.[68] Many mutations can occur in these genes and it is difficult to identify women who may be most at risk based on a single genetic defect. However, the use of DNA probes has found a valuable role in detection of important parameters.

To determine whether mutations may account for reduced expression of BRCA 1, Catteau et al.[67] screened the promoter region by sequencing. Although no mutations were detected, it was discovered that a new polymorphism consisting of a C to G base change within the β-promoter was present and that it is unlikely to play any role in disease. However, it was found to be suitable for rapid screening for genomic deletions within BRCA 1. The method involved amplifying the promoter region of

BRCA 1 by PCR, using the tumor DNA (obtained from breast cancer patients) as a template. Detection was by the amplification refractory mutation system (ARMS).[69] This allows rapid screening of germline mutations and may also be used to determine loss of heterozygosity in sporadic cancer.

Eccles et al.[70] screened 230 women for BRCA 1 mutations in order to establish the parameters on which to base a regional mutation analysis strategy. Mutation analysis by HD and single-strand conformational polymorphism (SSCP) was performed. Ten different mutations were detected in 17 families with three of these accounting for 59% of the cases. It has been proposed that mutation analysis may become more widely available if it can become cost-effective and if more detailed analysis could be attempted.

Overexpression of the c-myc gene leads to cancer development, especially of the breast.[71] Differential PCR and competing PCR have been developed for gene dosage quantification but both have a tendency to degrade DNA, whereas double-differential PCR, competitive-differential PCR and differential PCR are labor-intensive, expensive and time-consuming. With differential and competitive PCR, both degraded DNA and low competitor concentrations lead to over- or underestimation of gene dosages. In order to overcome these problems, methods using separate comparisons of two single-copy reference genes for any DNA sample (double-differential PCR), dilution series of the competitors (competitive-differential PCR) or sample DNA (differential PCR) have been developed. However, a direct double-differential PCR method was found to be sensitive and reliable.[71] In this approach, DNA fragments from two different single-copy reference genes and the target DNA fragment (c-myc) are amplified simultaneously in the same tube. The method, which involves the use of laser-induced CE is fast and allows the quantification of gene dosages without the use of synthetic competitors even when degraded DNA is present.

4.2.2 Colorectal Cancer[72]

In Europe, there are 210 000 new cases of colorectal cancer annually of which 124 500 will die. It is the second most common malignancy in men and the third most common in women. About a third of the patients have a primary tumor in the rectum with the majority of the remaining tumors occurring in the sigmoid colon. The prognosis is influenced by many factors such as age, gender, duration of symptoms, presence of bowel obstruction, tumor location, need for blood transfusion and the quality of surgical intervention.

A prognostic marker is a variable which provides prospective information on patient outcome which is complementary to the data obtained by the pathologist from the diagnostic sections and on which therapeutic decisions can be guided. The *ras* family is one of the most commonly detected oncogenes in human cancer (examples of *ras* genes are K-*ras*, H-*ras* and N-*ras*). The *ras* genes encode for 21-kDa proteins (p21S) which are found on the inner surface of the plasma membrane. *Ras* mutations may be an early event in leading to colorectal tumors.

PCR methods for the detection of *ras* mutations in DNA isolated from colorectal tumors have allowed prognosis to be determined faster. A *ras* mutation at codon 12 or 13 is associated with a poor prognosis. However, a poorer prognosis in patients with mutations in both *ras* and p53 was discovered.[73] The p53 tumor-suppressor gene is a commonly altered gene in human solid tumors.

4.3 Alzheimer's Disease

AD destroys nerve cells in the brain, which results in memory loss, decline of cognitive ability and incontinence in the later stages. An estimated 10% of people over 65 and about 50% over 85 suffer from some degree of AD.[74]

Abnormal genes for apolipoprotein E (apoE) appear to be a risk factor for the disease. ApoE codes for a family of lipoproteins and is involved in lipid transport in the brain.[74] On its own, apoE genotyping is not sensitive or specific enough to be used as a diagnostic test for AD, but it is used in classifying type III hyperlipidemia and in detecting genetic polymorphisms.[75] It has also been shown that the inheritance of one or more apoE 4 alleles increases the risk of developing artherosclerosis and AD.

Several apoE genotyping techniques have been used and these include minisequencing, SSCP, ASO probes and ARMS.[75] The ARMS technique, which comprises two PCRs each carried out using the same substrate DNA, is advantageous as it is rapid, easy to perform, nonisotopic and requires little sample manipulation.

5 THE BIOSENSOR APPROACH

5.1 Introduction

Figure 8 shows the main regions of a generalized sensor. The most important part of a sensor is the selective membrane/layer which interacts with the sample to produce useful information about the analyte.[76] To allow this, the interaction of the layer with the sample must be selective, a process which is achieved by immobilizing receptor sites for the analyte species in the layer. Mechanisms used for this include ion–cavitand "best-fit" interaction, electrostatic interactions, acid–base reactions, redox reactions, antibody–antigen interactions,

Figure 8 The main parts of a sensor. (Reproduced by permission of Dr D.C. Stone, Department of Chemistry, University of Toronto.)

enzyme–substrate interactions, ion-exchange reactions and nucleic acid hybridization.

5.2 Properties of an Ideal Sensor[76]

An ideal sensor should be specific for the analyte, sensitive to changes in concentration of the analyte, able to produce a rapid response, sturdy, i.e. it should have a lifetime of several months, small and of high precision.

5.3 Types of Sensors

The various types of sensor as classified by transduction categories are electrochemical (parameters monitored include potential, current and conductivity), piezoelectric (mass, viscosity, elasticity, density, conductivity), optical (absorbance, fluorescence, reflectance) and thermal (enthalpy, pyroelectric effect).

5.4 Biosensors for Nucleic Acids

The development of gene probe biosensors has been undergoing rapid technological modification, although it may still be considered to be in a state of infancy. Hybridization reactions have been detected with piezoelectric acoustic wave devices (the first detection was by a piezoelectric resonance sensor[77]) and the evanescent wave methods of total internal reflection fluorescence (TIRF) and surface plasmon resonance (SPR).[78] Readers who are interested in electrochemical devices are referred to references Millan and Mikkelsen[79] and Wilson.[80]

5.4.1 Acoustic Wave Methods

The launching of acoustic waves in solids at ultrasonic frequencies depends on the conversion of electromagnetic into acoustic energy.[81] The acoustic wave generated in piezoelectric materials is determined by crystal cut, thickness of material used and geometry and configuration of the metal electrodes employed to generate the electric field.[81]

Examples of acoustic wave devices include the thickness-shear mode (TSM) sensor (Figure 9), whereby the well-studied avidin–biotin interaction is utilized to measure frequency changes when the mass of substance on the sensor changes. It is also possible to have nonpiezoelectric acoustic wave devices such as the thin-rod acoustic wave (TRAW) sensor. Further details may be obtained in Thompson and Stone.[81] Recent uses of acoustic wave methods have included the detection of hybridization of a biotinylated 25-mer oligonucleotide probe with complementary and single-base mutated oligonucleotides[82] and a study of the various interactions of HIV-1 TAR RNA with tat-derived peptides[83] using a similar approach to that indicated for complementary strands.

TIRF has been used to monitor specific hybridization of labeled oligonucleotides whereby amino-ended 16- or 20-base DNA probes were covalently attached to the surface of optical fibers and hybridization to complementary fluorescein-ended oligonucleotides was detected.[84]

Measurement of nucleic acid hybridization by SPR has also been reported and, in one case, 17- or 50-base oligonucleotide probes were attached to silver-coated waveguides. It was found that a 97-base target sequence could be readily detected.[78]

5.5 DNA and Oligonucleotide Probe Arrays (Gene Chips)[80,85]

Probe arrays involving either DNA or oligonucleotides have been briefly mentioned in sections 2.1.4, 2.1.5 and 2.1.7. In this section, an overview of this potentially exciting area will be provided.

High-density arrays allow rapid sequence analysis of genomic samples and may also provide diagnosis of genetic and infectious diseases. The methodology

Figure 9 TSM sensor.

employed involves a combination of sequencing by hybridization (SBH), light-directed spatially addressable interrogation, combinatorial chemistry, confocal fluorescence microscopy, robotics and PCR. Advantages of this approach include reduced analysis times through multiplexing, the ability to produce any type of probe sequence and the possibility of having reusable chips which may be incorporated into nanofabricated structures.

Probe arrays have been utilized in several areas, some of which include the development of diagnostic tests for β-thalassemia,[86] studies of the breast cancer gene BRCA 1,[87] simultaneous analysis of the entire human mitochondrial genome[88] and monitoring of metabolic and genetic control of gene expression.[89]

6 CURRENT AND FUTURE DEVELOPMENTS

At present, many approaches to nucleic acid analyses are undergoing research in laboratories around the world. In this section, some of the interesting areas will be briefly discussed so as to give the reader a better perspective of novel developments.

A molecular hula hoop has been developed which is claimed to outperform PCR. The technique, called rolling circle amplification, uses a loop of DNA which sticks to either side of a target sequence and produces millions of copies of it until detection is achieved. This test may prove invaluable in forensic science.[90]

With respect to tumors, it is known that growth of these is dependent on angiogenesis. This has led to the development of new approaches to treatment and new agents directed towards tumor vasculature. One approach involves the use of endogenous inhibitory proteins to counter the angiogenic stimulus produced by tumors, an example of which involves gene transfer of DNA to angiogenesis inhibitors such as angiostatin or platelet factor 4.[91] Another approach to cancer treatment involves the delivery of genetically engineered cures directly to tumors through keyhole surgery. It is believed that this method could reduce unpleasant side effects. Based at the University of Dundee, the project is headed by Professor Sir Alfred Cuschieri, a pioneer of keyhole surgery, and Professor David Lane, who discovered the p53 gene which regulates the production of anti-cancer proteins.[92] A further development in chemotherapy involves the use of cisplatin, widely used to treat testicular and ovarian cancers. It binds to DNA in tumor cells but it also affects DNA in other rapidly dividing cells leading to toxicity. At the University of Edinburgh, Peter Sadler[93] has modified the drug so that it contains Pt(IV), which does not bind to DNA. However, when exposed to blue laser light, it reverts to Pt(II), which can now bind to DNA. By giving the drug to a patient and then illuminating the tumor cells with lasers, it may be possible to kill tumors without damage to other tissues. A 10-year investigation, involving 7500 adults, has just begun in Merseyside, UK, to see if people at high risk of developing lung cancer can be detected by a simple genetic test. Professor John Field believes that genetic alterations which can be detected in sputum may precede the development of lung cancer.[94]

As indicated previously, gene therapies are starting to have a major impact on the treatment of diseases. Research is continuing apace, some of which will be mentioned here. At several universities, researchers have demonstrated that transfer of the normal CF TR gene to nasal tissues of CF mice could restore some normal gene function. Although the mouse is not an ideal model for human CF, it marks the start of what could be an important breakthrough.[95] At Imperial College in London, Eric Alton and colleagues have shown that it is possible to deliver the gene to the lungs of patients with CF. At the Roslin Institute (where Dolly the cloned sheep was created), along with technology from Geron Corporation of California, research is under way to create transplantable, tissue-matched cells which could be used to provide treatments for diabetes, AD, Parkinson's disease and some leukemias.[96] It has also been reported that whole functional genes can also be added to cells and that pressure-treated veins can be successfully used in human heart-bypass patients.[97]

Transgenic therapies are also being investigated in the hope of ''creating'' human babies for infertile couples. At Imperial College, Robert Winston, a pioneer of fertility studies, is researching the effectiveness of inserting genes into sperm rather than into embryos.[98] In a similar approach, biologists in Hawaii have devised a method of producing transgenic animals. Their technique involves freezing and thawing sperm, mixing them with the foreign genes and then injecting them into eggs.[99]

Antiviral gene therapy, which stops the virus from replicating or expressing its genes, is also assuming increased importance. One method uses complementary ''antisense'' molecules: strips of nucleic acid bind to the DNA or RNA of the viruses to form a double helix. When this occurs, the RNA cannot produce protein molecules. Antisense molecules have been found to inhibit strongly HBV replication. Another approach is to use ribozymes, catalytic RNA molecules, which are involved in reactions which break down other RNA molecules. These have been found to be effective against HBV in vitro.[100]

Although much of this section did not deal with nucleic acid analysis per se, discussion of gene therapies was included as these developments all require accurate

methods for identifying and quantifying nucleic acid sequences.

ACKNOWLEDGMENTS

We express our gratitude to Dr David Stone of the Department of Chemistry, University of Toronto, for his assistance with section 5 and to Ms Blanca Granozio for her help with typing of the manuscript.

ABBREVIATIONS AND ACRONYMS

AD	Alzheimer's Disease
AE	Acridinium Ester

Drugs are administered to patients with the intention of achieving a planned therapeutic response. Yet drug prescription is a medical art because of the wide variation in individual responses to standard drug doses. In the 1960s, the field of pharmacogenetics emerged from the dedicated work of a small group of investigators who began to enrich the discipline of pharmacology by integrating it with human genetics. Pharmacogenetics provides the experimental framework to understand variability in human reactions to drugs and other exogenous substances as a function of intrinsic human genetic variability. The maturation of the human genome initiative has provided a wealth of primary genetic information and functional genomic data to fuel the understanding of genetic polymorphism and its functional consequences. Today, the field of pharmacogenetics is a well-integrated, worldwide network engaging a vast community of academic and industrial scientists.

One hallmark of pharmacogenetics studies is the large amount of genetic data that must be accumulated and integrated for high-resolution drug-response genotyping and subsequent phenotype profiling. This need for highly parallel genetic analysis has, in turn, fueled a demand for technical innovation to provide the tools necessary for its execution. The response has been a flurry of inventions in microfluidics and nanotechnology, some of which are scaled down versions of existing technologies, such as capillary electrophoresis and mass spectrometry, and some are completely new inventions. Outstanding in this technical revolution are DNA microarrays. Array technology has emerged as the most versatile and widely applied tool to support pharmacogenetics, for several reasons: arrays have the largest and most scalable capacity for parallel analysis, their inherent flexibility permits them to be used as independent analysis tools or as integrated components of more complex microfluidic systems and, finally, a wide variety of methods can be used to design and fabricate them. Pharmacogenetics is experiencing a period of rapid growth and definition. Arrays have proven themselves to be a technology capable of responding to the growing and changing needs of the current research

environment and are likely to be equally important as pharmacogenetics moves into the clinical arena.

1 INTRODUCTION

Drugs exert characteristic, reproducible effects when administered to individuals, and physicians have come to rely on them for the specific treatment of many human disorders. Most readers need not be convinced of the societal importance of these agents, but patients and physicians alike know that one individual may respond differently from another given the same dose of a drug. Such person-to-person variation in drug response is not a trivial matter. The analysis of the causes of natural variation in human drug response, the central problem of pharmacogenetics, requires a basic understanding of human pharmacology and human genetics.

The initial researches of a small cadre of dedicated investigators saw the emergence of pharmacogenetics in the 1960s as a new field of experimental science primarily concerned with reactions to drugs and other exogenous substances that occur because of a person's distinctive genetic makeup. The field has grown, particularly within the period from the late 1980s, into a well-integrated, worldwide network engaging a vast community of academic and industrial scientists with expertise in a broad spectrum of basic and clinical biomedical disciplines. Until recently, pharmacogenetic studies were usually limited to a few individuals and families in a research setting, but now such an investigation may be directed toward a large fraction of the human genome and involve simultaneous testing of multiple loci in many patients and healthy subjects. Such studies may, at times, be referred to as pharmacogenomics.

The establishment of laboratories dedicated to such large-scale pharmacogenetic testing is rapidly gaining momentum. This action has the attention of physicians who are in the front line of patient care, of those who are responsible for clinical laboratories and of academic and pharmaceutical scientists who are engaged in the discovery and clinical trial of new drugs. Because the genetics and the molecular basis of many pharmacogenetic traits are well established, because advance testing holds out high promise of improved patient care, and because the high potential for acceptance by the biomedical community, pharmacogenetics is in a strong position to link human genotyping and phenotyping rapidly with clinical application.

1.1 Historical Highlights

In an address before the British Medical Association in 1914,[1] Archibald Garrod proposed that enzymes were somehow implicated in the detoxification of exogenous substances. During the intense flurry of research stimulated by the rediscovery of Mendel's laws of heredity around 1900, Cuenot, from studies of mice, and Garrod, from human studies, anticipated the connection of enzymes (''diastases'') with the genetic material. Observations of physiological chemists, intrigued by the fate of chemicals in human subjects, had shown by this time that most drugs were excreted in forms that differed from those that were ingested. These observations, and Garrod's observations pertaining to a case of porphyria brought on by the hypnotic drug sulfonal, led Garrod to conclude that the ability of individuals to transform drugs into nontoxic conjugates, such as hippurates and glycuronates, protected them from the poisonous effects of these agents. Garrod was thus far ahead of his contemporaries in attributing unexpected drug responses of individuals to failure of their enzymes to detoxify these substances.

These ideas regarding the detoxification of chemicals surfaced again and again in Garrod's writings and teachings until the end of his life in the 1930s. He observed that substances in foods, in certain drugs, and in exhalations of animals and plants might produce effects in some persons wholly out of proportion to any they produce in most persons.[2] During the 1920s and 1930s, others began to scrutinize person-to-person differences in the perception of odor and taste.[3] For example, studies of ''taste blindness'' to the bitter-tasting substance *p*-ethoxyphenylurea was demonstrated to be a Mendelian character transmitted from parents to children as an autosomal trait. These deficits in sensory perception were the first indication of the high order of specificity to be expected in human response to chemicals, and the first to establish the heritable nature of such responses.[4]

By the time Garrod presented his ideas before the British Medical Association, chemists had identified virtually every major type of conjugation reaction that we know today. The exact dates of those discoveries is less relevant than the fact that they preceded by about 50 years the discovery of the other major category of detoxifying enzymes (P450s), commonly known as the microsomal enzymes or the drug-metabolizing enzymes. R. Tecwyn Williams, a pioneering pharmacologist at St. Mary's Medical School in London, saw evidence for a new, far-reaching principle of drug metabolism in the studies of the microsomal and conjugating enzymes, namely that the metabolic disposition of drugs in humans and animals occurs in two phases: first, oxidation, reduction, and hydrolysis, then conjugation, designating them as phase I and phase II metabolism respectively.

1.2 The Emergence of Pharmacogenetics

Until around 1950, progress slowed, but then several breakthroughs foreshadowing important events to come were made. In 1948, hemoglobinopathies S and C were identified and their mode of inheritance was determined. Hemoglobin S, the first hereditary protein variant to be identified, was also the first example of a variant protein in which replacement of a single amino acid residue within the protein molecule could be identified unequivocally with a change in the functional effect of the protein. In 1953, the double helix of DNA was described. A few years later, the chromosomes of humans were visualized and enumerated, and the chromosomal basis of one form of cancer (chronic myeloid leukemia) was identified. Following closely on the demonstration of polymorphic forms of hemoglobin S and C by electrophoresis, application of this technique to plasma proteins showed that protein polymorphism was a widespread phenomenon that merited further study.

New technologies that became available in the 1950s, combined with a more genetic approach to investigation, disclosed new relationships between the genetic control of responses to exogenous substances and their metabolic fate. Landmark studies of unexpected responses to primaquine, isoniazid and succinylcholine (suxamethonium) were the first to establish a link between drug response and heredity. The confluence of pharmacology, genetics and biochemistry noted in Arno Motulsky's 1957 seminal paper,[5] concerned with person-to-person differences in drug response that arise because of the unique genetic constitution of individuals, marked the true beginning of pharmacogenetics as an experimental science. In 1962, Werner Kalow published the first systematic account of the field, demonstrating the implications of heredity for responses of microorganisms, insects, and vertebrates, including humans, to environmental chemicals.[6] Since then, the characteristics of many more human traits of pharmacogenetic interest, too many to chart here, have demonstrated beyond any doubt that heredity is a remarkable prognosticator of unexpected response to drugs and other exogenous substances.

1.3 The Scope of Pharmacogenetics

Hereditary differences in toxicity or efficacy that result from exposure to therapeutic agents are usually considered as being within the province of pharmacogenetics, but if the unexpected response results from exposure to other chemicals, or to physical, climatic or atmospheric agents, it may be classified as ecogenetic.[7] Ecogenetics encompasses genetically conditioned responses to exogenous substances from any source and, as such, would include the pharmacogenetics of drugs used in medical practice. It should be noted, however, that, despite this distinction, the literature does not always adhere to this convention. When it is of interest to assess the characteristics of a given response, the criteria to be met in designing and executing a proper study to determine the heritability of the response in twins and families, and the distribution and incidence of genotypes and phenotypes in larger populations, are, in fact, identical for pharmacogenetics and ecogenetics.

Most well-studied polymorphisms derive from investigations of therapeutic agents, because these agents can be administered safely to individuals of all ages in defined amounts, and their disposition patterns can be measured. Historically, the drug-metabolizing enzyme polymorphisms are foremost in pharmacogenetics, and aficionados recognize these traits as the cornerstone of the field.[8] However, since medical drugs and other exogenous chemicals are biotransformed by the same enzymes, unexpected effects, as Garrod noted, may extend to foodstuffs as well as to sporadic disorders associated with exposure to chemicals under occupational and industrial conditions. The enzymes that metabolize exogenous substances may also metabolize hormones and other endogenous messengers that regulate cell signaling; consequently, mutations that affect those pathways may also cause differences in individual response. This evidence serves as an additional hallmark of pharmacogenetic and ecogenetic phenomena. The range of such phenomena is virtually without limit.

The administration of two or more drugs in combination may also set the stage for an unexpected drug response that depends on the genetic makeup of the recipient. The CYP2D6 (debrisoquine/sparteine oxidation) polymorphism is a particularly rich potential source of such interactions. This polymorphism affects the disposition of more than 30 therapeutic agents including β-adrenergic blockers, antidepressants, antiarrhythmics, neuroleptics, and various miscellaneous drugs such as phenformin, dextromethorphan, and codeine. Combined administration of two or more of these agents may result in an aversive interaction.

Smoking represents another environmental hazard that results in a variety of responses and disorders which may depend on genetic predisposition of smokers. In individuals with a genetic defect in α_1-antitrypsin, smoking is the most important environmental factor affecting the rate of deterioration of lung function.[9] Additionally, information is accumulating that a variant form or forms of CYP2A6 may exhibit impaired capacity to metabolize nicotine and may thereby protect against the effects of smoking by reducing the number of cigarettes smoked.[10,11]

Genetic predisposition appears to be involved as a hypersusceptibility factor for workers exposed to complex mixtures of chemicals. The formation of

aniline–hemoglobin adducts and excessive levels of methemoglobin can occur in those who are genetically ''slow acetylators'' after prolonged exposures to aniline derivatives.[12] The sporadic occurrence of urinary bladder cancer in slow acetylators many years after lengthy exposure to the aromatic amine carcinogens[13] employed in the manufacture of dyestuffs, plastics and electrical materials is a case in point.

Important clues to the role of heredity in unexpected responses to drugs and other chemicals are provided by individuals of different ethnogeographic origin. Perhaps the most familiar example is ''primaquine sensitivity'' occurring as a result of glucose-6-phosphate dehydrogenase (G6PD) deficiency among African, Mediterranean and Oriental persons. This is associated with sudden hemolysis, which occurs among susceptible males after exposure to any of some 200 drugs.[14] Other examples of ethnic specificity in drug response include the protective effect against alcohol-induced liver disease of a variant of aldehyde dehydrogenase (ALDH2) that is found in Japanese but not Caucasians[15] and the protective effect against alcohol-related birth defects of a variant form of alcohol dehydrogenase (ADH-3) occurring among African-Americans.[16]

While many of the examples cited above indicate that unexpected responses to exogenous chemicals may be mainly caused by a single (monogenic) factor, experience shows that variation of more than one hereditary element may contribute to the outcome. One example to illustrate the synergism that can occur between interacting factors is provided by a study of liver cancer caused by exposure to aflatoxin and hepatitis B among the Chinese. Aflatoxin exposure alone enhances the relative risk by approximately twofold, while infection with hepatitis B virus alone enhances the risk by approximately fivefold; however, combined exposure yields a 60-fold increase in relative risk of liver cancer. Hepatitis B infection, therefore, enhances the carcinogenic response among Chinese to aflatoxin by 30-fold.[17]

Nowadays, the scope for inherent variation in human response to exogenous chemicals is so great, and the pace of science so rapid, that it is difficult to stay abreast of new developments in the field. Although metabolic polymorphisms of drug-metabolizing enzymes appear most frequently in the literature, polymorphisms of other genes of pharmacogenetic interest, such as those that encode receptors, clotting factors, transporters and immunologic response proteins, appear increasingly frequently. In the 1990s, recombinant DNA technology has contributed immensely to our knowledge of pharmacogenetics by facilitating the development of sensitive and specific diagnostic methods for collecting molecular information about unexpected responses to drugs and other exogenous substances.

1.4 The Pharmacological Profile of Human Drug Response

Responses to a particular drug actually result from the physiological and biochemical attributes of cells that carry the necessary receptors in tissues of the recipient, but these responses are subject to modification by a variety of intrinsic and extrinsic influences.[4] The age, gender, weight and other physiological and pathophysiological attributes of the individual, including heredity, are important intrinsic factors that can modify drug responses in individuals. Foods and other dietary components, exogenous chemicals in household and workplace environments, the use of tobacco and alcohol, and drugs (prescription and nonprescription) themselves are some of the extrinsic factors that may affect these responses.

The response of an individual following administration of a drug (or after exposure to an exogenous chemical) is a complex process that is difficult to analyze. By reducing this process to pharmacokinetic and pharmacodynamic mechanisms, pharmacologists have devised a somewhat idealized picture of the response, which can be analyzed more readily. Pharmacokinetic mechanisms are those that affect the concentration of the drug at receptor sites and its time course of action (absorption, distribution, and elimination by metabolism and excretion) in the individual, while pharmacodynamic mechanisms refer to receptor-mediated and allied events. This maneuver also provides a framework well suited to discussion of the pharmacological nuances of variation in human drug response.

The response of an individual to most drugs can be thought of as a train of events that begins when the drug enters the bloodstream and ceases when the drug and its metabolites are completely eliminated. The administration of a drug, given in ordinary doses, is usually accompanied by a gradual rise in drug concentration in the blood that reaches a peak or steady state; if no more drug is given, the concentration steadily declines until the drug and its metabolites are eliminated. If the drug attains a concentration within the therapeutic range, the characteristic response is expected. If the concentration reaches a level above or below that range, either a toxic response or the absence of the expected response may occur. For unexpected responses, experience indicates that there are two likely explanations. If the drug concentration in plasma is above or below the therapeutic range, one would anticipate a pharmacokinetic mechanism is responsible for the unexpected response, but if the concentration is within the therapeutic range, a pharmacodynamic defect is a more likely explanation.

Consequently, from the pharmacological viewpoint, unexpected drug responses to drugs and other exogenous

substances may be regarded to a first approximation as peculiarities resulting from a defect in either the pharmacokinetics or the pharmacodynamics of the drug.

1.5 The Genetic Profile of Human Drug Response

Geneticists, in contrast to pharmacologists, might consider a drug as an environmental agent on which individuals exert important differential effects; therefore, they might regard an unexpected drug response as a reflection of a genetic difference between normal and abnormal responders.[4] Geneticists, as a rule, are more interested in looking for differences that discriminate individuals rather than focusing on universal similarities, and they would seek to explain an unexpected drug response by drawing on the gamut of information from the normal and affected responders as well as from their biological relatives. From the information obtained, they would attempt to determine the relative contributions of heredity and environment to the unexpected response.

Genetic defects that cause unexpected drug responses occur sufficiently often in many populations to enable members to be divided into two or more relatively common types of responder. Hereditary variation in which such sharply distinct qualities coexist in a given population is referred to as genetic polymorphism. This term is usually used in genetics to refer to genetic loci for which variants occur with a frequency of 1–2% or greater, but in pharmacogenetics the definition is better based on phenotype. This issue has been the source of some discussion[18,19] and is considered further below (section 2.3). To avoid contradictions between pharmacogenetic usage and genetic theory and concepts, this article will refer to the polymorphisms linked to human responses to drugs and other exogenous substances as ''pharmacogenetic polymorphisms''. Pharmacogenetic polymorphism may include variation produced by chromosomal aberrations, which are detectable by cytogenetic techniques, but most result from smaller, genic lesions.

To assess the contribution of heredity to pharmacogenetic polymorphism, unexpected drug responses are explored at all levels of gene action, from the gene molecule itself, to the individual and their biological families, to populations of individuals. Broadly speaking, hereditary differences in drug response are characterized by two types of information: the genetics that characterize the polymorphic phenotypes and their molecular basis. The latter includes a description of the genetic heterogeneity at the level of DNA and of the protein variants that explain the trait. By studying a given trait from several points of view, the relative influence of human ecology and heredity and the mechanisms by which they occur are ascertained. For these purposes, the concepts and techniques of human genetics, biochemistry, population and molecular genetics, and epidemiology are used in concert to analyze pharmacological, toxicological and epidemiological observations of individuals, twins, families and larger populations.

1.6 The Rationale and Aims of Pharmacogenetics

Pharmacogenetic investigation often begins with an anecdotal clinical observation on one or a few individuals who have experienced an unexpected response to a specific drug, or with an epidemiological observation on a group of individuals who have developed a disorder associated with occupational exposure to a chemical or complex mixture of chemicals.[4] The main goal of pharmacogenetics, simply put, is to use knowledge gained in understanding the influence of heredity on human sensitivity (or resistance) to exogenous chemicals to avoid the occurrence of such responses in susceptible persons. Therefore, while the early detection of cancer of environmental origin, for example, may do little to change the outcome in an affected person, identification of the trait that led to its initiation may prevent its occurrence in others.

A number of practical problems can arise in the design and execution of pharmacogenetic studies. A complete assessment of the causes of a given trait may be exceedingly difficult to achieve, may require the collaboration of scientists with differing expertise or may require resources not readily available. For example, epidemiological evidence may suggest a disorder (say bladder cancer) is caused by a particular agent (or agents), but the agent or agents usually cannot be identified unequivocally solely by epidemiological evidence; clinical observation may suggest an adverse reaction is caused by a certain drug, but the physican who contemplates investigation of the reaction by further exposure of humans to the offending drug may face insurmountable ethical and methodological constraints; susceptibility to a toxicant can often be more thoroughly studied under highly controlled conditions in animals than in humans, but studies in animal models are slow and expensive, and animal responses do not necessarily translate closely to those in humans.

Establishment of definable end-points for the investigation of specific differences between normal and abnormal responders poses another problem. Consider the evaluation of drug treatment of hypertension as a case in point. In this instance, the definitive end-point would be measured by the difference in the incidence of strokes and cardiovascular disease between normal and abnormal drug responders, but this would probably occur years after the trait is recognized and modifying treatment undertaken. Another example of pharmacogenetic interest

concerns the evaluation of individual variation in susceptibility to cancer associated with prolonged exposure to an occupational carcinogen. The definitive end-point in this case is the difference in cancer incidence many years later between hypersusceptible and normal responders exposed to the carcinogen. It is apparent that accomplishment of trials to determine definitive end-points might require studies extending over many years involving many individuals and large populations, and the payoff is not guaranteed.

Investigations with more limited goals designed to measure intermediate or short-term changes in biochemical and molecular markers may lessen some of these difficulties. Biological markers that can detect early and subtle differences in individual response would be necessary for this purpose. The most suitable are markers that can be detected in small samples of tissue or body fluids that are accessible to sampling; they should be expressed differentially in accordance with differences observed in normal and abnormal responders and they should have a low probability of spontaneous change.

Several advantages accrue to study designs that focus on the use of intermediate- or short-term biomarkers. First, the marker could be used to document and characterize the heterogeneity in response of individuals to a given drug, and to determine its distribution in individuals, families, and other populations of interest. This would indicate the frequency of a given trait, its mode of inheritance, and its ethnic and geographic specificity. Second, the markers could be used to identify the genes and the mutations responsible for the trait in susceptible people. This information would reveal the molecular basis of the trait and would aid in elucidating disordered physiological mechanism(s) that account for the aberrant response. It would shed light on the mechanism of the response to the agent in normal (wild-type) responders. The marker would also be of further use in the development of noninvasive, inexpensive diagnostic tests to determine the phenotype and genotype of individuals for the trait. Third, for agents used in medical therapy, identification of the molecular basis of specific traits and the elucidation of their underlying mechanisms would rationalize the selection of specific agents for susceptible (or resistant) individuals and make it possible to tailor drug regimens to the individual patient. Fourth, since the exact cellular site that is defective must be known for rational design of therapy, the information obtained in the first three study parameters would help to guide discovery of new drugs and to improve the design and conduct of their clinical trial. Finally, studies with markers could have wider implications for patient welfare by alerting physicians, clinical scientists, and others engaged in patient care to the importance of biomonitoring of individuals who suffer sporadic illnesses while ingesting certain drugs and of individuals who become ill after prolonged exposure to toxic chemicals associated with a specific occupation or a particular environment.

An important goal of studies with intermediate- and short-term biomarkers is validation of the markers by demonstrating their correlation with definitive end-points. It is reasonable to expect that these biomarkers will enable differences in human susceptibilities to exogenous chemicals to be detected, or suspected, at an early stage of exposure, and the liability of susceptible persons to be predicted long before the definitive end-point is reached. It follows that studies using such biomarkers could be accomplished in a much shorter time and at a much lower cost than those aimed at determining definitive end-points.

1.7 Testing Pharmacogenetic Hypotheses

Exploring the pharmacogenetics of unexpected drug responses can be a formidable task. No hard and fast rules exist to guide the investigator's advance planning, but there are some general principles that are widely applicable.[4] Experience indicates that the response of an individual to a drug and its inherent variation are best considered in light of the pharmacokinetic and pharmacodynamic mechanisms that define the disposition and actions of drugs in individuals (see section 1.4). Insights into the relative importance of the pharmacokinetic and pharmacodynamic phases of the response to the overall variability in the response to a given drug in a heterogeneous group of drug responders can often be gained by a preliminary pharmacokinetic analysis.

In general, an experimental approach is almost inevitably based on testing a main hypothesis and one or more auxiliary hypotheses.[20] The novice may, in fact, proceed with only a vague notion of the hypothesis being tested, but skilled investigators know that it is advantageous to have thought about it explicitly. Auxiliary hypotheses are set forth as reasonable alternatives in case the main hypothesis proves false. Investigators should also remember that, for every discovery made with innovative approaches, many important advances are made simply by recognizing that an established method or familiar technique devised for one application can be used for another. In some cases, it is possible for the investigator to design a single experiment that decides the fate of a given hypothesis.

1.8 Summary

Individual differences in human responses to therapeutic agents and other exogenous chemicals often result from some derangement of the genetic material that may be transmitted from one generation to the next. The scientific

study of the effects of heredity on drug response is the province of pharmacogenetics. Its main purpose is to explain the toxicological effects of the derangements by rigorous characterization of their biochemical and molecular basis. In this way, it is hoped to understand the causes of human susceptibility to exogenous substances and avoid the occurrence of unexpected drug responses in susceptible persons.

2 THE CHANGING SCENE

2.1 Human Protein Diversity

Proteins are vital to virtually every process of biological importance because of their capacity to bind other proteins and small molecules with high sensitivity and specificity.[21] The assortment of proteins that resides in cells and tissues requires that the synthesis and targeting of these molecules is carried out with a high level of fidelity according to the well-defined set of instructions encoded in the genes. The properties of distinct proteins ultimately define the link that exists between the genetic constitution of a given individual and his or her response to drugs. It follows that a structural alteration in a given gene, or an error in carrying out the program of instructions encoded in the gene, might reasonably be expected to change the structure or the amount of the protein synthesized, or its final destination. Briefly, mutation could cause an unexpected drug response.

The occurrence of G6PD deficiency, succinylcholine sensitivity and isoniazid acetylation polymorphism, detected in the 1950s, was regarded as a serious threat to drug usage in medical therapy, requiring further investigation. Examination of the pharmacological defect and molecular genetic basis of unexpected drug responses set the agenda for subsequent research, and studies quickly showed that changes in protein structure resulting from genetic change altered human drug responsiveness wherever it was sought, among proteins with widely disparate functions, in health and disease.

2.2 Some Biochemical Generalizations

By the 1970s, Harris and colleagues had sought to examine the genetic causes of human protein diversity from the biochemical, chromatographic and electrophoretic characteristics of proteins associated with certain single gene disorders.[22] Certain hemoglobinopathies and enzymopathies provided the best models for this purpose because information about structural gene mutations was matched by physiological and pathological data. Evidence suggested that mutations might range from a single base change within the coding region of a gene to large deletions that removed a large part, or all, of a gene. A single polypeptide chain that was affected by different mutations in the coding region might thus be represented by several distinct alleles. Most hemoglobinopathies, for example, could be ascribed to missense, nonsense, or frameshift mutations of the coding region of globin genes. Among the enzymopathies, observations suggested that allozymes (i.e. enzymes encoded by allelic loci) generated by point mutations and small deletions would usually display highly homologous amino acid structures and might have similar enzymatic properties, whereas larger deletions resulted in drastically shortened, nonfunctional gene products, or the total absence of the product.

Post-translational modifications were recognized as additional sources of the structural modification of proteins.[22] Should such a modification occur by an enzyme-mediated process, as had been established for oxidation of sulfhydryl groups or the addition of carbohydrate or phosphate groups, or by the cleavage of the polypeptide with loss of a terminal amino group, or a larger part of the chain, it too could be subject to genetic variation.

Unfortunately, the available biochemical data were inadequate to yield a detailed picture of the molecular basis of protein heterogeneity. For instance, a change that alters the charge on a protein can be detected by electrophoresis, but since two-thirds of amino acid substitutions are neutral, they will not change the net charge on the protein and will not be detected in this way. As a consequence of the inability of the standard methods of protein characterization to distinguish variation owing to genetic variation at the level of translation from that which occurs post-translationally, or nongenetically, information regarding the genetic basis of protein diversity was very meager.

2.3 DNA Polymorphism: Some Practical Matters

The analysis of genomic DNA reveals that the human genome is highly polymorphic. Sites that exhibit alternative sequences at a particular chromosomal site can be used as genetic markers for the site, or for the chromosome bearing the site. Three types of polymorphic site are useful for identifying individuals who are predisposed to unexpected drug responses: those within genes that determine drug response, those within short variable DNA repetitive sequences (known as variable number tandem repeat (VNTR)) and those within microsatellites. When such a site is associated with a given trait and tracked within families and larger populations, it can provide information about inheritance patterns and the prevalence of the trait. Polymorphic sites can be studied by restriction fragment (Southern) analysis to survey chromosomal sites for polymorphism, or by DNA sequencing to determine the precise location of base changes that

define a polymorphism. Southern analysis cannot resolve polymorphisms that differ by only one or a few bases, and neither can it identify the polymorphic base, whereas the size and boundaries of the polymorphic site can be precisely determined with the polymerase chain reaction (PCR) used in DNA sequencing. This second approach is essentially a refinement of the first and is preferred in many applications.

Since the development of molecular techniques, remarkable progress has been made toward identification of genes responsible for pharmacogenetic polymorphisms and toward understanding the molecular basis of quite a few of these polymorphisms at the DNA level. Most of the progress has related to traits attributed to a single polymorphic gene, many of which have been cloned and sequenced.[23] For some, the gene of interest has been expressed in heterologous expression systems in quantities sufficient for biochemical and pharmacological characterization.

The VNTRs or minisatellites of the human genome may be repeated 100 times or more in different persons. Many VNTRs, numbering in the thousands, are well characterized. Restriction fragment analysis will produce different size fragments proportional to the number of repeats in the VNTR. Where the identification of traits has been slowed for lack of a sufficient number of suitable genetic markers, the use of VNTRs should alleviate this constraint.[24]

A number of genes have been found to incorporate microsatellites within them.[25] Microsatellites are stretches of repetitive DNA sequences; if mutated, they are capable of disrupting cell function. Such mutations may serve as hereditary markers of genomic instability that may increase individual susceptibility to certain cancers. For example, the loss of microsatellite DNA from the androgen receptor gene has been associated with prostate cancer. This event is of pharmacogenetic interest because a paradoxical response to antiandrogen therapy (i.e. stimulation of tumor growth instead of the inhibition expected) was exhibited by a patient.[26]

The extent of protein diversity in natural populations is immense, but the abundance of DNA polymorphism in the human genome appears even greater. Analysis of genomic DNA reveals the presence of a large number of these polymorphisms. On average about 1 in 500 nucleotides differs between two randomly chosen alleles. Only about 5–10% of these polymorphisms is detected by restriction analysis, and frequently these polymorphisms are unrelated to a clinical phenotype. This phenomenon has been demonstrated for the CYP2D6 polymorphism by Skoda and colleagues,[27] who examined genomic DNA from 53 persons using a total of 20 restriction enzymes to fragment the DNA in different ways. Tests of 13 enzymes yielded 14 allele-specific polymorphic patterns at the *CYP2D6* locus, while the other seven enzymes revealed none. This study and others (see references in Skoda et al.[27]) show that DNA polymorphisms are often functionally silent at the protein level, having no detectable phenotypic effect.

It follows that information about a given genotype is insufficient for unambiguous identification unless combined with information about the associated phenotype. Further evidence pointing to the importance of identification of phenotypes arises from numerous sources. These include studies of the potential dissociation of phenotype from genotype observed in certain races[28,29] and in certain families,[30] the lack of resolution of heterozygous and homozygous subjects by standard metabolic phenotyping procedures,[30] the different phenotypes for different substrates for a given polymorphism,[31,32] structure–function relationships,[33] gene–gene interactions,[34] and the patterns of disease[35] associated with polymorphisms attributed to genes with closely similar sequences.

We should also point out that since the vast majority of pharmacogenetic traits, unlike most genetically determined human disorders, usually cause no recognizable effect on the health of predisposed individuals, the importance of phenotype takes on added significance. Only when susceptible persons suffer an unexpected response from exposure to certain drugs, dietary constituents or other environmental agents is their predisposition revealed. Fortunately, many of the polymorphisms associated with genetically variable human drug-metabolizing enzymes, can be detected in advance with the aid of a number of test probes that are suitable for human phenotyping by in vivo or ex vivo testing procedures. A partial list of these probes is presented in Table 1.

For the reasons stated above, pharmacogenetic polymorphisms must be defined on phenotypic grounds. Any comprehensive description of a given pharmacogenetic polymorphism should include information about the phenotype that characterizes the polymorphism and the genotype(s) that explain the polymorphism.

2.4 Molecular Heterogeneity of Pharmacogenetic Interest

Recombinant DNA techniques rapidly superseded standard methods of protein characterization for genetic analysis during the 1980s, and reports of the molecular characteristics of numerous enzymes, including the P450 (CYP450) enzymes of drug metabolism, soon appeared in the literature. Because of their specificity for endogenous steroids, fatty acids, and prostaglandins, as well as for many drugs, environmental pollutants, and carcinogens, the CYP450 enzymes had already attracted a great deal of

Table 1 Test probe drugs for human phenotyping of human drug-metabolizing enzyme polymorphisms

	Test probe	Refs.
Phase I enzymes		
Aldehyde dehydrogenase	Acetaldehyde	36
Alcohol dehydrogenase	Ethanol	16
CYP1A2	Caffeine	8
CYP2A6	Nicotine, coumarin	11, 37
CYP2C9	Warfarin	8, 37
CYP2C19	Mephenytoin, omeprazole	8
CYP2D6	Dextromethorphan, debrisoquine, sparteine	8
CYP2E1	Chloroxazone, caffeine	8
CYP3A4	Erythromycin	8
CYP3A5	Midazolam	8
Serum cholinesterase	Benzoylcholine, butrylcholine	38
Paraoxonase/arylesterase	Paraoxon	39, 40
Phase II enzymes		
Acetyltransferase (NAT1)	*Para*-aminosalicylic acid	41
Acetyltransferase (NAT2)	Isoniazid, sulfamethazine, caffeine	42
Dihydropyrimidine dehydrogenase	5-Fluorouracil	43
Glutathione transferase (GST-M1)	*Trans*-stilbene oxide	44, 45
Thiomethyltransferase	2-Mercaptoethanol, D-penicillamine, captopril	46
Thiopurine methyltransferase	6-Mercaptopurine, 6-thioguanine, 8-azathioprine	47
UDP-glucuronosyl transferase (UGT1A)	Bilirubin	48, 49
UDP-glucuronosyl transferase (UGT2B7)	Oxazepam, ketoprofen, estradiol, morphine	50, 51

attention among biochemical pharmacologists. Additionally, metabolic studies conducted during the mid-1970s with sparteine or debrisoquine suggested a polymorphic variant of CYP450 might be responsible for the poor metabolism and unexpected responses of susceptible persons. Other studies with mephenytoin suggested a variant of a distinctly different CYP450 appeared to explain the poor metabolism and unexpected responses of susceptible persons to this drug. In 1982, the complete primary structure of a mammalian CYP450 was reported from recombinant DNA studies, and this breakthrough prompted a great deal of further investigation.[52] A recent count shows that more than 150 isoforms of CYP450 have been characterized as products of different genes, and at least 30 different human CYP450 enzymes have been purified, cloned, sequenced and characterized. Of these, less than ten (namely 1A1/1A2, 2A6, 2C19, 2D6, 2E6 and 3A4) are responsible for oxidation of most drugs and other substrates in the human environment.[8]

A chronology of selected human pharmacogenetic polymorphisms that have been identified since the emergence of pharmacogenetics in the 1950s is given in Table 2. It includes a cross-section of polymorphisms: several drug-metabolizing enzyme polymorphisms, several receptor polymorphisms (e.g. malignant hyperthermia, vasopressin resistance, insulin receptor resistance) and polymorphisms of some other protein variants of pharmacogenetic interest. The table also draws attention to the time that elapsed between the initial description of the inheritance of a given polymorphism and the explanation of the polymorphism at the DNA level.

As Table 2 shows, molecular genetic studies identified some of the molecular defects in CYP2D6* associated with poor metabolism of sparteine and debrisoquine some 11 years after the trait was discovered. CYP2D6* (sparteine/debrisoquine oxidation) polymorphism has stimulated an enormous amount of investigation and we now know that this polymorphism results in three separable phenotypes: poor metabolizers, extensive metabolizers, and ultrarapid metabolizers. The CYP2D6* poor metabolizers have an impaired capacity to metabolize more than 30 drugs and are homozygous for an inactive or deficient CYP2D6 enzyme that has been modified by truncation or missense mutations of the gene *CYP2D6**. In contrast, ultrarapid CYP2D6* metabolizers possess an enhanced capacity to metabolize these drugs because they possess more than one copy of an amplified *CYP2D6**.

Pharmacogenetic polymorphism is well established for the genes of several other CYP450 enzymes including 1A1, 2C9, and 2C19, and is rapidly accumulating for 1A2, 2A6, 2E1, and 3A4.[8] Most of the genetically variant CYP450 enzymes occur as high- and low-activity (or null) isoforms that may confer individual susceptibility to the toxic effects of environmental chemicals including carcinogens. Molecular genetic studies have identified the genes that encode these enzymes as well as numerous allelic forms of them.

Table 2 also lists several drug-conjugating enzymes. During the 1990s, considerable progress has also been

Table 2 Chronology of pharmacogenetics

Polymorphism	Inheritance described	Mutation described	Elapsed time (years)
Succinylcholine sensitivity	1957–60	1990–92	33
G6PD deficiency	1958	1988	30
Long QT syndrome	1957–60	1991–97	34
Acetylation	1959–60	1989–93	30
Malignant hyperthermia	1960–62	1991–97	31
Glucuronosyl transferase	1966–69	1992–?	26
Vasopressin resistance	1969	1992	23
Aldehyde dehydrogenase	1969	1988	16
Debrisoquine oxidation	1977	1988–93	11
Retinoic acid resistance	1970	1991–93	21
Thiopurine methyltransferase	1980	1995	15
Mephenytoin oxidation	1984	1993–94	9
Glutathione transferase	1986	1990	4
Fructose intolerance	1986	1988–95	2
Insulin receptor resistance	1988	1988–93	0
Androgen resistance	1990	1990	0
Glucocorticoid remediable aldosteronism	1992	1992	0

made in the molecular genetic analysis of these enzymes. Prominent members of this group are the polymorphic forms of acetyltransferases, glucuronosyltransferases, glutathione-*S*-transferases and thiopurine methyltransferase.

Receptor proteins represent another subset of proteins (see Table 2) with enormous potential to influence human sensitivity to exogenous substances.[4] Comparatively few receptor polymorphisms have been studied so far, since this group of proteins has not yet been explored in the depth achieved with the drug-metabolizing enzymes. Prior to the 1980s, the existence of receptors and receptor subtypes was customarily defined by differences in their interactions with drugs, but this approach did not achieve outstanding success in establishing receptor heterogeneity on a molecular plane. Based on their location and mechanistic features, two main types of pharmacological receptor are recognized: those that are located in the cytoplasm and with a locus of action within the cell nucleus, and those that insert into the cell surface and span the membrane. Cell surface receptors are involved in the actions of most drugs and endogenous first messengers; being on the cell surface, they can bind biogenic amines, protein and polypeptide hormones, autocoids, neurotransmitters and environmental chemicals. The nuclear (cytoplasmic) receptors, by comparison, interact with relatively few, albeit important, first messengers that can enter the cell, such as the steroid hormones. The techniques of molecular biology have enabled sufficient amounts of a given protein to be produced for biochemical and pharmacological characterization and have greatly refined and extended the genetic analysis of receptor heterogeneity.

2.5 The Effect of Mutations on the Gene Product

Mutations have been observed to have two main effects on the gene product: they can cause the production of a structurally variant protein with altered functional properties or the production of a fully functional protein in altered amounts, usually reduced, although traits attributable to increased amounts of protein have been described.[53,54] Mutations that cause the synthesis of structurally variant proteins usually occur within the coding region of the gene, whereas mutations located within the promoter and other regulatory sequences usually alter protein quantity. Most pharmacogenetic polymorphisms result from point mutations, or other small genic lesions that lead to a functional change in a given protein, or loss of all or most of a gene. As these polymorphisms occur at specific genetic loci and within specific regions of the gene, the ability to detect and determine the associated specific structural change(s) allows for diagnosis.

Knowledge of the biochemical, pharmacological or toxicological features associated with an unusual phenotype can sometimes lead to inferences about the identity of the gene and the properties of the allelic variants responsible for the phenotype. Many pharmacogenetic polymorphisms were characterized by this approach long before molecular genetic techniques were developed. For example, observation of low levels of urinary acetylated metabolites of isoniazid suggested that an acetyltransferase, or acetyltransferases, with impaired capacity to acetylate isoniazid accounted for the isoniazid-induced nerve damage seen in susceptible patients. Biochemical studies documented the presence of functionally impaired forms of this drug-conjugating enzyme, which led to the

identification of genetically slow acetylators as a separate class of drug responders in human populations. The properties of acetylating enzymes isolated from tissues of slow acetylators were found to be closely similar to those from normal (rapid) acetylators, which suggested that a small genic lesion, possibly a point mutation, or even a small deletion, might account for slow acetylation of isoniazid.[55]

At the time of the early biochemical studies, the existence of acetyltransferase variants could only be inferred; however, with the aid of molecular genetic techniques, the genes for acetyltransferase have been cloned and sequenced, and expression studies have demonstrated the existence of such variants, affirming predictions made some 30 years earlier. We now know that humans possess two drug-metabolizing acetyltransferase loci, and that variation at the *NAT2** locus is responsible for isoniazid acetylation polymorphism. We also know that the coding region of this gene is the site of multiple mutations that confer slow acetylation ability on individuals. A total of nine single nucleotide changes have been identified within the coding region of *NAT2** that account for more than 95% of slow acetylator alleles extant in human populations. Since these mutations occur singly and in combinations of two and three, they yield more than 20 *NAT2** slow acetylator alleles.[56]

The *NAT2** polymorphism is an example of polymorphisms within the coding region of the gene, but recently polymorphisms within regulatory regions have also been described. The genetically polymorphic form of CYP2E1 with enhanced activity that is associated with ethanol ingestion and with obesity represents an example of a regulatory polymorphism.[57] CYP2E1 is recognized as an important enzyme for the detoxification of ethanol and many other xenobiotics and some drugs, including chloroxazone. Chloroxazone is a test drug that is used to detect intersubject variation in CYP2E1 activity by in vivo and ex vivo procedures. Toxicological studies suggest a possible role for this enzyme in alcohol-related disease among African-American women. Analysis of the upstream region of *CYP2E1* revealed a DNA insertion, 100 base pairs (bp) long. The presence of this insertion mutation significantly increases CYP2E1 metabolic activity as measured by chloroxazone hydroxylation, but only among persons who are obese or have recently consumed ethanol, or both. The frequency of heterozygous carriers of the mutation is 31% in African-Americans and 6.9% among Caucasians. This polymorphism in the regulatory region not only enhances CYP2E1 activity but is sufficiently common to affect susceptibility to CYP2E1-related disorders in at least two ethnic populations.

These examples comprise only a small part of the molecular genetic studies that have been conducted on pharmacogenetic polymorphisms, They afford insights into the genetic basis of phenotypic differences in human drug response, but it is prudent to avoid attempting to classify the effect of the mutation on the gene product from incomplete information. For example, a trait that appears, on limited study, to result from a quantitative defect in protein synthesis, may, on further investigation, be found to be caused by a structurally abnormal protein that disintegrates because it is inherently unstable or undergoes rapid proteolysis in the cellular environment.

2.6 Summary

Proteins are the molecular links between the genetic constitution and the drug response of the individual. The presence of a biologically active protein molecule at its native site in cells and tissues requires the synthesis and targeting of the molecule to occur in accordance with the well-defined program of instructions encoded in the genes. An alteration in the gene or failure to carry out the instructions with complete fidelity could produce a variation in the structure, function or final destination of the protein, any of which might alter the profile of drug response in the individual. Despite the remarkable advances in the understanding of pharmacogenetic polymorphisms at the molecular level, the dissociation of the phenotype from the genotype that is observed under various circumstances requires that both the phenotype and the genotype be characterized for unambiguous identification of a given polymorphism.

3 GENETIC PROFILING USING DNA MICROARRAYS

3.1 The Origin of DNA Microarrays

DNA microarray technology has its origins in Edwin Southern's method described in his landmark article ''Detection of specific sequences among DNA fragments separated by gel electrophoresis'' published in 1975.[58] There, he described how to combine the specificity of DNA restriction endonucleases with gel electrophoresis and sequence-specific hybridization to probe genomic DNA for its sequence composition. Restriction enzymes were used to generate controlled, predictable genomic DNA fragmentation, while gel electrophoresis provided an efficient, economic approach to arraying the fragments by size. The arrayed fragments were transferred by ''blotting'' onto a membrane support with a high affinity for nucleic acids, affording ease of handling and analysis of the same fragmented sample with a variety of probes. Finally, the complementarity of DNA base pairing as it occurs during hybridization permitted access to specific sequence information in the genomic DNA sample when it was hybridized with probes of known sequence.

The simplicity, elegance, and economy of the Southern blot facilitated its adoption into many molecular biology laboratories in a minimum amount of time. It not only became a standard laboratory protocol but also quickly began evolving into a diverse collection of hybridization-based analytical techniques. In 1977, for example, Alwine[59] described the Northern blot version of Southern's electrophoresis: a hybridization probe method to analyze messenger RNA (mRNA) sequences that provided the link between genomic sequence and functional mRNA expression analysis. Alwine's technique was also quickly adopted. Improvements and innovations in Northern and Southern blotting continue to simplify, refine and generalize the analysis of the broad range of sample types studied today.

Continued development in the Southern blotting method has greatly enhanced understanding of genomic DNA structure and organization. For example, routine use of Southern blotting led directly to the realization that restriction enzymes do not yield an identical DNA fragmentation pattern from every genomic DNA sample. Polymorphic variability occurring in the primary sequence occasionally ablates or creates new restriction sites in a genome. Restriction digestion and hybridization probing these samples results in altered banding patterns, called restriction fragment length polymorphism (RFLP).[60] Alex Jeffreys responded to this observation by developing ''DNA fingerprinting'' assays based on the Southern blot method.[61] DNA fingerprinting relies on measuring complex combinations of RFLP fragments to document the degree of variability or similarity among individual genomic DNA samples. For this purpose, Jeffreys developed probes that hybridize with a type of DNA locus he discovered during his study of the myoglobin gene. These sites are characterized by VNTRs called minisatellites.[62,63] These repetitive sequences, found throughout the human genome, are termed hypervariable because they exhibit variable numbers of repeats both within a single locus and between loci. VNTRs are still the most common markers used both for genomic DNA mapping and individual identity genotyping. Routine Southern blotting has resulted in the development of a large collection of informative VNTR probes suitable for many analytical applications.

Hybridization analysis using immobilized DNA includes ''dot'' blots and ''slot'' blots. Dot and slot blots are named for the circular and slotted well shapes in the templates used to present test samples to a membrane surface. They eliminate the need for restriction digestion and electrophoretic resolution steps by depositing samples of DNA to be tested directly onto a hybridizable membrane surface. Dot blot methodology is faster and easier for hybridization screening than Southern blotting, especially when many samples are to be screened simultaneously using specific sets of hybridization probes. They can accommodate DNA samples too small or too damaged to undergo the purification, restriction digestion and electrophoresis demanded for Southern blotting, but tend to be somewhat less sensitive and informative than Southern blots since they do not provide RFLP information and are more prone to nonspecific background hybridization.[64,65]

The invention of PCR permitted the development of the ''reverse dot blot'' in which the probe collections, rather than the DNA test samples, become the immobilized species on the membrane surface. DNA to be analyzed is prepared by PCR amplification of the region of interest, labeled with a detectable marker and hybridized to the array of immobilized probes.[66] The reverse dot blot concept led to the idea of generating generic arrays of probe sets that would allow high-throughput screening applications, as in routine molecular diagnostics. Commercial reagent suppliers began to develop generic products in response to the demand for common genomic analyses. The basic components that enabled individual investigators to customize reverse dot blot probe sets for their own applications have also become commercially available to investigators and are widely used throughout the molecular biology community.[67,68]

As the density of information derived from efforts to sequence, map and identify human genes increased, so did the demand for analytical tools capable of exploiting this information. DNA microarrays were developed in response to this demand. Southern[69] was the first to describe parallel, in situ oligonucleotide synthesis as a means of generating oligonucleotide probe arrays on solid supports for highly parallel hybridization analysis. Southern's method uses standard nucleotide synthetic reactions to synthesize the oligonucleotides. The reactions are carried out in a movable chamber, which provides a physical barrier between the reaction chamber and the intended synthesis area.

This method of generating microarrays has been modified in several different ways since it was introduced. In one, photochemistry and photolithography have been incorporated into the oligonucleotide synthesis.[70] This technique uses novel monomeric reagents with photolabile protecting groups that are activated by light exposure; this permits controlled, localized array synthesis to be achieved. In another approach, piezoelectric nozzles and ink jet heads have been modified to ''print'' DNA synthesis reagents directly onto substrates that support in situ oligonucleotide synthesis localized by surface chemistry.[71]

In a sequence of events reminiscent of the Southern blot evolution into the Northern blot method, arrays of immobilized complementary DNA (cDNA) and expressed sequence tags have emerged on the heels of

DNA oligonucleotide arrays to profile mRNA expression patterns. In these ''spotted'' arrays, purified cDNA clones or PCR products are micropipetted as an array on a substrate surface and immobilized by one of a variety of covalent or noncovalent methods.[72–74]

DNA microarrays are distinguished from reverse dot blots by their relatively high probe density, miniature size and use of solid, nonporous supports. Solid supports offer many functional advantages for arrays, as they become integrated components in automated, high-throughput assay systems. Rigid supports, particularly those that are optically transparent and thermally conductive, are more practical than large, flexible membranes for interfacing with automated fluid delivery or printing equipment, which introduce analytical samples, detection reagents and washing solutions. They also best accommodate the automated scanning systems that are used to image the arrays.

3.2 DNA Microarray Capabilities and Limitations

DNA microarrays already occupy niches in nearly every area of nucleic acid analysis. Both comparative or quantitative measurements and direct sequence analysis can be achieved, and microarrays have been designed and fabricated for applications as diverse as genomic mapping,[75] clone library screening, gene expression profiling,[76] genotyping and reference-based sequence checking (resequencing).[77,78] However, despite their universal appeal and versatile functionality, DNA microarrays are analytical tools and should be evaluated in that context. The probe sets that make up an array and their associated functional assays are designed differently depending on the intended application. Arrays provide only a single component of complex biological assays that depend on well-integrated methods for isolation, amplification and labeling of the target to attain high sensitivity and high-resolution detection.

Sequence information is obtained from microarrays by decoding the complementarity between known array probe sequences and the partners they capture from a solution of labeled, hybridized test targets. Genotyping to identify a given polymorphism in a gene or DNA fragment can be used to illustrate how an array provides sequence information. A successful genotyping assay depends on developing maximum discrimination at the single nucleotide level among sets of closely related probes. This aim is best accomplished by selecting probe sets that display maximal signal uniformity and intensity as perfectly complementary duplexes. A genotyping result is interpreted by comparing positive signals that are anticipated from these duplexes with those obtained from sets of closely related mismatched probes. This method provides a background reference that controls for hybridization specificity and permits confident interpretation of the hybridization result. Because mismatched probes do not hybridize well under optimal assay conditions, positive signals that display high intensity against a low nonspecific background are readily perceived.

During the development and fabrication of an array, candidate probes can be evaluated for optimal performance by using them to genotype target DNA samples that have been genotyped by a separate reference method. Confidence in genotype assignment can be improved further by selecting probes to interrogate the target sequence on both strands of target DNA and then combining the information to make a composite base call. Such an assay is not finished until an algorithmic analysis of its output is shown to be concordant with that of the reference for the same sample set. Discrepancies between the two sets of results must be resolved and the source of any difference must be attributed to the candidate or reference probes.[79]

Defining acceptable performance specifications for a genotyping assay requires that a number of considerations be factored together. Because array hybridization and, therefore, genotyping quality are not likely to be completely uniform across complex hybridization arrays, it is critical to establish acceptable limits for the range of reporter and background signals observed; because the occurrence of different polymorphisms may differ in a given sample, individual polymorphisms should be weighted by the frequency at which each phenotype occurs, to achieve reliable prediction of composite genotypes; and because methods of target amplification and labeling of reporter molecules are variable, they may contribute significantly to the range of quality and confidence that will be observed in the results obtained.

Hybridization efficiency and hybrid stability both increase with probe length, and DNA array probes used for expression profiling tend to be longer than those used for genotyping.[80] This permits maximum detection capability for sequences of low abundance in complex RNA mixtures. Mismatch discrimination decreases as probe length increases, but high-resolution sequence discrimination is not a high priority in most expression profiling studies. Quantification of RNA abundance depends on hybridization signal intensity being directly proportional to hybridization target abundance, and maintaining this relationship depends on having a well-designed target preparation strategy. Linear target amplification methods such as in vitro transcription and ligase chain reaction coupled with controlled label incorporation into the amplified target have been quite successful in meeting this requirement. Appropriate sets of controls for use as internal standards for calibration of the assay can readily be developed.[76,81]

The provision of effective gene expression profiling requires comparative and quantitative measurements of RNA. The target sequences in a given sample of RNA will represent a large concentration range of various transcripts, and the goal is to quantify them as accurately as possible. Strategies for expression profiling to meet this objective must maximize detection sensitivity for unique, low-abundance transcripts in complex hybridization mixtures dominated by highly expressed transcripts.

Effective expression-monitoring probes demonstrate hybridization sensitivity over a wide range of target concentrations. Global optimization of hybridization performance for expression-profiling arrays is as challenging as for genotyping arrays. The large number of probes in an array, coupled with the innate variability of the RNA pools used in the hybridization, make it impractical to test concentration dependence and sequence specificity for each probe independently. Consequently, other broad-based performance optimization strategies have been pursued. Designs that have proven successful for expression profiling include multiple hybridization probes for each mRNA sequence of interest, and related mismatch probes to estimate the contribution of nonspecific interactions to each specific hybridization signal. Redundancy also permits probes to be tailored to detect 3′ and 5′ ends and specific exons in mRNAs. These probes may be useful to gauge the quality of RNA and cDNA target preparations and to dissect splice variants or other closely related members of gene families. It has been reported that from four to twenty probe pairs (one fully matched to a target sequence and one mismatch control in each pair) may define the limits of useful redundancy in oligonucleotide-based gene expression profiling arrays.[76]

A second, more common type of DNA microarray for expression profiling uses cloned cDNA or PCR products amplified from cDNA rather than oligonucleotides as capture probes. These DNA products are collected as libraries and robotically deposited onto chemically prepared solid substrates as addressable hybridization arrays. The original method for making these arrays relied mainly on noncovalent associations between the support surface and the one or two kilobase lengths of deposited DNA to keep the clones immobilized during hybridization.[72,82] However, this method has rapidly evolved to include a wide variety of substrate surfaces, coupling chemistries and methods of delivering the probe DNA accurately and reproducibly to the surface. Both commercial and private efforts to optimize these ''spotted'' arrays are yielding ever more uniform and reproducible arrays. One advantage over oligonucleotide arrays that is gained with immobilized cDNA is that any clone from a cDNA library, whether or not it has been sequenced, can serve as a probe to screen for complementary sequences in other RNA sources. In contrast, some primary sequence must be known for each target to generate synthetic oligonucleotide probes for an array. Hence, these two types of expression-monitoring array actually provide complementary functions. The other obvious contrast is that cDNA, because of its length, is likely to hybridize not only with its intended target but also with other closely related sequences, such as those within gene families. Oligonucleotide probes are more easily customized to discriminate among related sequences and so may offer a more refined expression profile for individual related sequences.

Microarrays based on cDNA or oligonucleotides differ fundamentally in how their experimental outputs are analyzed. Typical cDNA arrays are hybridized with differentially labeled cDNA pools generated from two separate RNA sources. For example, RNA may be harvested from untreated cells grown under a standard set of conditions and the cDNA produced from this RNA pool may be labeled with one fluorescent dye. A second RNA sample is then harvested from the same cell type after it is treated with a chemical or grown under a different set of conditions, and the cDNA is labeled with a second dye. Once the two cDNAs can be distinguished by their labels, equal amounts are mixed and hybridized competitively to the same cDNA array. The ratio of one dye signal to the other at each probe will reflect relative differences in abundance between the two RNA samples for the gene represented.

In contrast, a typical oligonucleotide array is usually hybridized with a single RNA pool labeled using a single reporter molecule. A measure of the hybridization intensity at each probe is obtained using internal calibration standards. The success of this approach depends on having a way to normalize the signal at each probe for any nonspecific background contributing to the signal intensity. This is usually achieved, as mentioned previously, by pairing a closely related, mismatched probe for each specific probe in the array. In addition, use of a redundant pair of probes for each target helps to average out this variability.

As the amount of available information about expressed genes accumulates and the sequence of the entire human genome emerges, successive generations of DNA microarrays have become increasingly dense in probe sites. The result is a dramatic increase in information gathered from each profiling experiment, and greater insight into the complexities of cellular biology. This gain is accompanied by target preparation requirements of increasing complexity to access the information that an array offers. What the useful limit to hybridization complexity will be is not yet clear. Entire cDNA libraries and the entire yeast genome have been successfully hybridized to DNA microarrays to yield large volumes of information

from single experiments, but a method for whole genome typing of a target organism in a single hybridization is still out of reach. Currently, PCR or some alternative strategy is required to achieve informative human genotyping by microarray hybridization. Variability in performance potential among hybridization probes and nonspecific interactions on the array surface (both within targets and between targets and probes) limit full reconstruction of such a complex target from a single hybridization.

The measurements made using DNA microarrays are very difficult to optimize to a tightly specified standard because of the high density of information and its parallel nature. It is equally difficult to validate individual probes globally in microarray hybridization assays at every data point, since it is impractical to check every point by a reference assay method. Statistical approaches to solving this problem include checking a selected sample of output data by an independent assay and testing statistical variability within and among repeated assays. A second strategy to validate the results of microarray hybridization is based on the integration of sets of complementary hybridization controls directly into the array.

The process of establishing and validating DNA microarrays is further constrained by the fact that their functional use and performance evaluation must be in the context of a broader, integrated system. That is, peak array performance occurs when probe design has been tuned to the chosen target, the labeling method is efficient and reproducible, and the imaging system is sensitive, calibrated and well matched to the reporter molecule used. Finally, sensible output analysis depends on the specific assay application and the control elements built into the assay. Arrays, especially very high-density arrays, are most efficiently used with automated interfaces that integrate all assay steps from sample preparation, through hybridization, data acquisition and output analysis. Ultimately, full microarray assay automation should become available from sample input to output of the genotype or expression profile. Progress in microarray development has been impressive, but an equally impressive amount of work remains to be done before these methods will be fully robust clinical tools.

3.3 Predictive Testing with DNA Microarray Assays

Predictive testing based on DNA microarray profiling is not available at the present time, although it is widely promoted. True predictive pharmacogenetic testing relies on having broad individual genotyping capability and integrated rational therapeutic management strategies for disease guided by genetic predisposition and risk profiles. Reaching this goal will require more than just technical development. The pharmacokinetic and pharmacodynamic end-points that are used to describe therapeutic indications and responses today need to be integrated into a coherent picture and translated into molecular end-points. Our fundamental knowledge of the physiological effects of therapeutic agents must also be reduced to a molecular level. Pharmacogenetic traits are remarkable prognosticators of individual responses to drugs, exogenous chemicals and xenobiotics, but our present level of understanding of the pharmacokinetic and pharmacodynamic effects of drug response at the molecular level is rudimentary.

Our current state of knowledge of human drug response stems largely from retrospective genetic analyses guided by phenotypic responses to specific drugs. As these observations are studied in greater depth, it is becoming clear that few, if any, phenotypic outcomes will be reliably predicted from simple genetic analyses at a single locus. It is also clear that even when complex genetic analysis becomes more sophisticated and widely available, predicted phenotypes will still represent a potential rather than a certain outcome. Translating predicted potential into an outcome prediction will still depend on factoring environmental variables such as diet, age, drug use, health status and environmental exposure history into the equation. It is also likely that clinical monitoring of therapeutic responses will not be replaced by, but rather will be guided by, predictive testing. For example, a patient may have a genotype that predicts metabolic tolerance for a cardiotoxic medication with a narrow therapeutic index. The drug may be given to him because it most effectively targets his genetically profiled therapeutic need. However, blood monitoring for toxic drug levels may still be required since the effect of illness on his metabolic performance is not predicted by his genetic profile.

Two radically different approaches have been proposed for developing therapeutics based on known molecular mechanisms for individuals whose phenotypic responses are projected from their individual genetic profiles. One approach is to generate a high-resolution map of the human genome using characterized polymorphic markers, especially single nucleotide polymorphisms. Once the map is available, large-scale population epidemiology and case–control studies are expected to provide high-quality associations between genetic markers, specific disease and therapeutic response phenotypes. These population-derived markers are anticipated to be useful for projecting individual outcomes and risk assessments. The alternative approach has been to find individual genes that give rise to distinctive phenotypes and study them in depth. Each gene is fully characterized for polymorphic variability and each variant is characterized by its impact on the phenotype. As this information is assembled, phenotypes may be recognized that cannot be explained by known genetic

variants, and genetic variants will be recognized that do not lead to separate phenotypes. These observations may, in time, lead to the discovery of new functional relationships with other genes. Both strategies claim some success and both contribute to our basic understanding of human genetic variability. Whether one approach is superior to the other remains to be seen.

3.4 Emerging Applications of Microarray Technologies

Microarray technologies are useful for many applications requiring direct nucleic acid sequence analysis, sequence comparisons or quantitative comparison among nucleic acid samples. Limitations exist where direct hybridization analysis is not the best-suited approach, as for analysis of trinucleotide expansion (fragile X and Huntington's disease) and microsatellites. Microarray applications are not limited to human genetics but can also be used for target organisms such as yeast, model organisms *Arabidopsis thaliana* and *Caenorhabditis elegans*, viral and bacterial human pathogens, mouse, rat and ape genomes, and a wide variety of other agricultural plant, pest and animal targets. It is likely that this entire spectrum of genomic studies will ultimately contribute significantly to clinical applications of pharmacogenetics. Human gene complementation applied to regulatory pathways in model organisms has a strong track record for predicting parallel human biology. In addition, these models provide powerful pharmacokinetic and pharmacodynamic discovery assays and toxicology screening systems. Continued expansion of its technical foundations is expected eventually to provide combined genomic profiling for genetic variability and functional expression profiling capability as single assays.

All early microarray assays relied on hybridizing a labeled target or test nucleic acid directly to probes covalently linked to a substrate surface in an addressable format. Signal location provided sequence information about the hybridization target; signal intensity provided semiquantitative information about target abundance in the hybridization solution. The need for improved quantitative and discriminative performance from microarray assays has led to rapid innovation and improvement in a number of different areas: in the design of initial arrays and assays; in modifications in nucleotide chemistry,[83] linker chemistry,[84] substrate preparation chemistry[71] and hybridization solution compositions,[85] which permit ever-increasing refinement and control over assay performance; in improved array components, which permit performance of increasingly complex and sensitive analyses; and in the coupling of primary hybridization assays to secondary enzymatic processes, such as primer extension and enzymatic mismatch cleavage, to increase the quantity and quality of information yielded by a single assay.[86,87]

Applications of microarrays to genotyping include typing of samples for known sequence variants and discovery of new polymorphisms in specific targets, such as drug-resistant pathogens and functionally variant forms of known genes. Arrays for these types of test perform best with probes that have similar hybridization behavior, and efforts to design such probe sets have proven successful. Hybridization to complete collections of oligonucleotide probes of a given length shows a wide range of variability that correlates directly with individual nucleotide composition. An alternative method of design that avoids such variability is to target array probe sets to a narrow range of thermal stability. Probes designed by this criterion may still vary in length, but they show much more uniform behavior within a single set of hybridization conditions. Discrimination of the hybridization signals of fully complementary hybrids from the uninformative signals that result from associations between partially matched nucleotide fragments is much improved by this approach. Further refinement of hybridization uniformity has been obtained by incorporating nucleoside analogs that smooth thermal stability and disrupt intra-probe hairpin structures and mismatch associations. These assay modifications help to maximize discrimination among specific sets of related nucleotide sequences. These developments have been important in the effort to provide arrays for sequencing applications where samples are hybridized to an array of oligonucleotides that reconstructs a consensus sequence.[83,88] Probes that fail to hybridize to this type of array indicate the presence of a polymorphism in the test target sequence that causes loss of complementarity with the consensus probe.

The density of information from microarrays has increased in parallel with technical advances in robotic microfluidic delivery systems and photolithographic techniques for fabrication of arrays. The result is an increased yield of information from single assays, but this comes at the cost of the increased complexity in preparing a test sample for hybridization in a way that uses the array optimally. For genotyping or sequencing applications, this usually means that a large number of PCR products must be generated in essentially equal quantities and labeled as uniformly as possible with a reporter molecule that permits hybrid detection. For expression-profiling experiments, RNA must be quantitatively isolated from the test source, amplified enough to permit rare mRNA detection but not enough to lose the quantitative relationships among the various mRNA species. Uniform labeling of samples with a reporter molecule is critical to keep the hybridization signal of each mRNA proportional to its abundance. These analytical demands have been met with a variety of innovations in array design and target labeling strategies.

As microarray technology has advanced, an abundance of new and challenging analytical applications have arisen, for example cancer biology. Many cancers are characterized by nucleic acid changes in somatic cells. The challenge here is in finding efficient ways to present the very limited amounts of test sample available from a biopsy to arrays for hybridization analysis. Loss of heterozygosity is another important somatic cell change indicative of cancer progression that can be detected only by quantitative genetic analysis. Detection of drug-resistant pathogens is another quantitative analytical problem, since genotypes of resistant organisms emerge against a background of susceptible genomes. Similarly, assessment of host selectivity for a given pathogen demands the detection of virulent subtypes occurring at low frequency in a background of benign genotypes. Studies to document human genetic variability for association studies to link our genes to our environmental responses on a population basis require true high throughput genotyping for large numbers of genetic markers. These studies present challenges in the technical aspects of genotyping by microarrays and in bioinformatics.

3.5 The Future of Microarrays and Allied Technology

Despite remarkable innovation and rapid technical improvement in microarray technology, several significant limitations in its application remain. Methods of fabrication need improvement to enhance their utility and reduce costs of construction. The availability, utility and efficiency of bioinformatics methods used to access, process and store array information are also limited. Preparation of an adequate quantity of high-quality, labeled target DNA for a given assay still presents a major difficulty in the use of DNA microarray technology. This is particularly problematic for gene expression profiling, where quantitative output is important and the relative abundance of the starting materials must be preserved during amplification and labeling. In addition, as more and more of the genome is accessed for profiling and genotyping, the problem of preparing amplified material from all relevant sites in the genome presents significant technical and economic burdens. At present, methods of multiplexed PCR amplification are not sufficiently robust or reliable to permit quantitative production of target material on a genomic scale. In addition, the cost of enzymatic amplification and labeling reagents for large-scale target preparation is significant.

A better method for highly parallel genetic analysis is needed. One with single molecule sensitivity that eliminates both the requirement for target amplification and the need for a target to be chemically modified or labeled for its detection would be ideal. Innovations in array construction, sample nucleic acid preparation and detection hold this promise for a second generation of microarray technologies. For instance, Heller and colleagues have developed arrays with bioelectronic chips that are electronically addressable.[89] An electric current can be used to address each feature of the chip, enabling direct capture probe immobilization as well as control of hybridization stringency with the target molecules. This type of array has been shown vastly to accelerate target capture rate by using electric fields at each probe site to overcome the passive diffusion that previously had been a rate-limiting factor.[90,91]

A number of completely different approaches to array-based genetic analysis show considerable promise. One consists of a DNA microarray combined with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS) detection. Technical development of this system is moving ahead rapidly. MALDI/TOFMS detects sequences by measuring their mass, which is attractive because it does not require separate labeling of the target. Initially, the principal limitation of MALDI/TOFMS lay in its inability to discriminate large molecules with sufficiently high resolution, but strategies have been devised that mitigate this problem. A second disadvantage of MALDI/TOFMS is the relatively large amount of sample material needed to achieve reliable results. MALDI/TOFMS systems are commercially available, and the development of methods to apply this system to determination of genotypes is accelerating.[92,93]

Another unique approach to microarray technology uses fiber optic bundles to support an array of microbeads that are coated with DNA capture sequences. Each bead is individually associated with a single fiber in the bundle, and hybridization targets labeled with fluorescent dyes are hybridized to the beads. The one-to-one concordance of bead to fiber in the bundle permits every bead in the hybridization array to be addressed and reported individually.[94,95]

DNA microarrays, even at their current state of technical evolution, are proven analytical tools with sufficient capacity to meet future needs of genetic assays. There are, however, technical challenges that must be met before they can reach their full potential, as well as significant challenges in bioinformatics and information management that applications of microarrays have created. Microarray technology generates such vast quantities of information that powerful databases, only now emerging, are necessary to analyze the information obtained and to store it in a format that is accessible. New concepts in database mining will be necessary to relate these large, complex sets of genetic data to the phenotypes recorded in clinical databases. The new knowledge gained from the

discovery of associations between genotypes and phenotypes of individuals in response to exogenous agents should enable clinical applications of pharmacogenetics to develop.

3.6 Summary

Currently, microarray applications span all aspects of molecular biological investigation, enabling the collection of large amounts of genetic data from comparatively few experiments. At present, microarrays are used mainly as research tools to determine the most effective ways of gathering information for individual genetic profiles and management of unexpected responses to medical therapy and environmental substances. With further development, they should contribute substantially to point-of-care analysis and therapeutic management. The full potential of the technique will only be realised when bioinformatics to analyze large datasets are also fully developed.

4 THE OUTLOOK FOR GENOMICS IN PREDICTIVE MEDICINE

4.1 Options for Treating Genetic Disorders

The care of patients with genetic disorders involves many of the approaches to diagnosis and treatment that are used in other medical specialities, but the focus in medical genetics is more toward prevention or avoidance of the disorder. Presymptomatic (including prenatal) diagnosis, genetic screening programs and genetic counseling are concepts central to this approach.

Options for treatment of genetic disorders at the environmental level routinely involve a combination of restriction, replacement and removal of the toxic substance. Restriction of potentially toxic environmental substances could, for example, involve restriction of certain foods or other dietary constituents. Fructose is one of the major constituents of human diets, and intolerance for this sugar is represented by a polymorphism in the aldolase B gene.[96–98] Continued ingestion of fructose or its congeners is required to establish the disease, but the wide distribution of these substances in foods and some drugs places genetically susceptible persons at constant risk from an avoidable nutritional disorder. The fish odor syndrome (trimethylaminuria) is another example of variability in human response to foods.[99] A polymorphism in the gene for flavin-monoxygenase 3 accounts for some cases of this trait.[100] Trimethylamine, a metabolic product of numerous foods that contain choline or carnitine, confers the smell of rotting fish on affected persons, with devastating educational, economic and social consequences. Management of trimethylaminuria remains empirical; the main recourse for affected persons is dietary restriction to reduce their intake of trimethylamine precursors. This may require avoidance of foods rich in choline, such as eggs, liver, soya beans, and marine fish.[4]

Restriction of certain therapeutic agents is an option that is commonly applied by physicians to avoid adverse drug reactions in genetically susceptible patients. Individuals with a deficiency in G6PD (Table 2) must avoid oxidant stresses such as those that accompany intake of antimalarials, sulfonamides and an extensive list of other drugs; failure can result in hemolysis of red blood cells. Individuals with thiopurine methyltransferase deficiency (Table 2) usually must receive much smaller doses of 6-mercaptopurine, 6-thioguanine, and 8-azathiopurine if they are to avoid toxicity (bone marrow suppression) by these agents. These drugs are mainstays of antileukemic and immunosuppressant therapy. Those with this inherited deficiency are intolerant to these agents and may suffer acute and delayed responses that can be life threatening.[46]

Toxicity resulting from exposure to cigarette smoke in persons afflicted with α_1-antitrypsin deficiency has been mentioned above (section 1.3). Avoiding cigarette smoke can prevent its destructive effects on the lungs, which result in emphysema and chronic obstructive lung disease.[9]

Replacement of deficient gene products or even of organs is also utilized in the treatment of genetic disorders: for example, replacement of coagulation factor VIII in hemophilia A, of α_1-antitrypsin in persons deficient in this factor or of pancreatic islet cells in some forms of diabetes mellitus.

The option to remove the toxin from the environment of susceptible persons is taken in hemochromatosis, a common disorder of iron metabolism[101] that affects 1 in 300 persons of northern European descent. Most cases of hereditary hemochromatosis are attributed to a polymorphism of *HFE*, which results in substitution of tyrosine for cysteine at codon 282. The disease, untreated, causes liver cirrhosis, heart failure, diabetes and arthritis and leads to early death; treatment by phlebotomy to remove excess iron allows affected persons to live a normal life span.

4.2 Many Pharmacogenetic Polymorphisms are Exceptions to Experience with Single Gene Disorders

The point was made above (section 1.6) that pharmacogenetic polymorphisms usually have no perceptible effect on the health of predisposed persons, unlike other genes involved in human diseases. The frequent occurrence

and ethnic specificity of human pharmacogenetic polymorphisms are further features that set them apart from many human disease genes.

The gravity of effects that may be in store for susceptible persons is only revealed by exposure to certain drugs, dietary constituents, or other environmental toxins; without this exposure, their genetic predisposition is invisible. Most people perceive heredity as having an important effect on health and disease, but may be unaware of the relevance of genetics to their own responses or of person-to-person differences in response to environmental toxins. The belief is widely held that unexpected responses to these substances are entirely linked to the toxin, but we know that the drug recipient is not a passive participant in these events.

Hemochromatosis (1/300)[101] and cystic fibrosis (1/2000 to 1/2500)[102] are regarded as highly prevalent genetic disorders in human populations, but they are rare compared with many pharmacogenetic polymorphisms. Polymorphisms of *G6PD*, *CYP2D6*, *CYP2C19* and *NAT2* illustrate this point very well.[103] G6PD deficiency is a sex-linked trait that affects 5–10% of dark-skinned races. Males of African, Mediterranean, and Oriental descent are particularly susceptible. Globally, this deficiency is estimated to affect more than 400 million persons.

CYP2D6 polymorphism has been the subject of many population studies. More than 95% of deficient alleles responsible for CYP2D6 poor metabolizers have been identified (see section 3.2). Eleven nucleotide changes belonging to seven *CYP2D6* allelic variants describe the extent of ethnic variation in people of Africa, Asia and Europe.[104,105] The prevalence and ethnic specificity of the ultrarapid CYP2D6 phenotype described recently indicates that Swedish and German populations possess 1–2% of this phenotype, whereas the frequency is higher in Spain (3.5–5%); the carrier (heterozygote) frequency in Ethiopia and Saudi Arabia is also very high (15–20%).[106]

The prevalence and ethnic specificity of CYP2C19, another polymorphic P450 enzyme (Table 2), also varies quite remarkably. CYP2C19 polymorphism, previously named mephenytoin polymorphism, is of major importance because of its role in elimination or activation of drugs such as omeprazole, an antiulcer drug, proguanil, an antimalarial drug, and several barbiturate hypnotics and sedatives.[107] The frequency of poor drug metabolizers owing to the m1 (*CYP2C19*2*) variant is high in Japanese (13–23%) compared with Caucasians (4%). Another variant, m2 (*CYP2C19*3*), occurs in Japanese and Africans but has not been detected in Caucasians. The wild-type and the m1 and m2 variants account for almost 100% of the variation in Asian poor metabolizers, but these and additional variants account for only about 92% of the variation in Caucasians.[108]

Studies of the prevalence and global distribution of *NAT2** polymorphism have involved well over 10 000 subjects in dozens of populations since the polymorphism was identified in the 1950s (Table 2 and section 2.5). The percentage of slow acetylators ranges from 80% or more in Egyptians and certain middle Eastern populations to 20% or less in Japanese and Canadian Eskimos. Populations of European and African origin are, with few exceptions, characterized by intermediate percentages of the slow acetylator phenotype.[55] Molecular studies indicate that *NAT2** allelic frequencies are neither uniformly nor randomly distributed across different populations. For instance, the frequency of the rapid acetylator *NAT2*4* allele is approximately 20–25% among American and European Caucasians, 36% among African-Americans, 42% among Hispanics, and 66–70% among Asiatics from Hong Kong, Korea and Japan. The distribution of *NAT2** alleles for slow acetylation varies with racial origin; in Caucasians, three alleles (4, 5B and 6A) account for about 95% of all *NAT2** alleles, whereas in Oriental populations the 5B allele becomes rarer (5% in Hong Kong Chinese to <1% in Japanese) and 6A (20–30%) and 7A/7B (7–16%) are most frequent.[103]

4.3 Emerging Applications of Pharmacogenetic Interest

Areas of focal importance for the pharmaceutical industry and for those engaged in the development of microarray and allied technologies include adverse drug reactions, diagnostics and targeted therapies. The versatility and broad capability of microarray technology permits it to be applied to any of these areas for the study of variation in genes, pathways and targets associated with disease.

The main challenge for the immediate future is to devise reliable methods and techniques for identifying and scoring all types of genetic variation in the human genome. Several strategies and technologies for identification of such variation at the molecular level are being developed (sections 3.3–3.5). Questions have been raised as to whether microarrays have the capability to identify different types of mutation, and whether they can distinguish heterozygotes. Cronin et al.[79] examined the first question in a study of *CFTR*. They found that the gene, composed of 27 exons, contained more than 500 widely distributed mutations, including transitions, transversions, insertions, deletions and polymorphisms. Two microchip arrays (480 and 1480 probes of 14–16-mers) were used to scan exon 11. Ten unknown genotypes assigned by these assays were identical with PCR product restriction fragment analysis.

Hacia et al.[77] looked at detection of heterozygotes predisposed to breast and ovarian cancer in a study of *BRCA1*. They found that it comprised 22 exons spanning 100 kb and contained more than 110 mutations

(frameshift, nonsense and missense) distributed throughout the gene. A microchip array with 96 500 20-mer nucleotides used to scan 3.45 kb of exon 11 accurately diagnosed 14 of 15 patient samples, and no false positives were found among 20 controls. Even though the full potential of these devices is not yet realized, these studies, among the first to report applications of microarrays to genes associated with disease, demonstrate very clearly the capability of this technology for genetic analysis.

The analysis of pathways affected in disease is another emergent application of this technology. Pathways that regulate cytokine signaling, insulin signaling and apoptosis are among those identified for early investigation. Targets of high priority for study include G-protein transmembrane receptors, ion channels and transcription factors. The nucleic acids targeted for these and some other emerging applications of focal interest are mRNA (cytokine induction, tumor suppression), DNA (cytokine mutants), germline DNA (*BRCA1*), yeast DNA (barcoding mutants), DNA of human immunodeficiency virus (protease-resistant polymorphisms), mitochondrial DNA (natural polymorphisms) and *CYP2D6* and *CYP2C19* DNA (drug-metabolizing enzyme polymorphisms).

4.4 Linking Human Genotyping to Clinical Applications

The ultimate goal of pharmacogenetics is to gather information that explains unexpected responses to exogenous chemicals and that prevents or avoids the occurrence of these responses in genetically susceptible persons (see section 1.6). Among all the possibilities emerging from, or accelerated by, the human genome initiative,[109] pharmacogenetics is an area that may rapidly bring the predictive prospects of human genotyping into the clinical arena. In essence, a given pharmacogenetic polymorphism is characterized by three types of information. These are the genetics (mode of inheritance, allelic frequencies, and ethnic specificity), the molecular basis (genes responsible, and their mutation spectrum) and the medical or biological significance of the polymorphism.

Ethnic specificity not only provides information about unique features of a population that is of evolutionary interest, but may also explain situations of therapeutic interest. Consider the administration of a drug metabolized by the CYP2D6 system, such as codeine, to patients of different ethnicity. Codeine is an analgesic prodrug, the effectiveness of which depends on its conversion to morphine. This conversion is impaired in poor *CYP2D6* metabolizers, and consequently they do not get pain relief from ingestion of codeine.[110] For the same reason, they are also protected against dependence on oral opiates such as codeine.[111] The failure to respond to codeine would, consequently, be more prevalent among Africans and Caucasians (5–10%) than among Asians (<1%). Unexpected neurotoxicity from amphetamine and its analogs (e.g. 3,4 methylenedioxymethamphetamine, also known as ''ecstasy'') as well as interactions with other drugs subject to *CYP2D6* polymorphism would likewise be expected to occur more frequently among Africans and Caucasians than in Asians.[112]

The analysis of the molecular basis for unexpected responses of ultrarapid *CYP2D6* metabolizers to codeine follows a similar line of reasoning. The ultrarapid metabolizers have enhanced capacity to metabolize codeine and hence may exhibit exaggerated responses, such as abdominal cramping, fuzzy vision and disorientation.[113] Because ultrarapid metabolizers occur more frequently among Hispanic, African and Saudi Arabian than Asian populations,[106] the former groups would be more likely to experience *exaggerated* responses to codeine.

4.5 Summary

Genetic disorders with abnormal reactions to environmental factors are no less treatable than many other disorders treated by physicians. These genetic disorders are treated by restricting access to, replacing and/or removing the toxic substance from the environment of the susceptible persons. Pharmacogenetic polymorphisms are invisible until their effects are revealed by exposure of individuals who harbor them to environmental toxins; microarrays and allied technology provide the means to screen for these polymorphisms and to identify susceptible individuals before they are affected.

5 SUMMARY: PROGRESS IN PHARMACOGENETIC TESTING

Individual susceptibility to the effects of drugs and other exogenous chemicals is often the consequence of some derangement of the genetic material that may be transmissible from one generation to the next. The scientific study of these effects is the province of pharmacogenetics. The main purpose of pharmacogenetics is to understand the causes of unexpected responses to exogenous substances and to prevent or avoid their occurrence in susceptible persons. Prior to the development of recombinant DNA technology, the role of changes in the genetic material and the consequent production of aberrant proteins, or failure to produce proteins, in disease could only be inferred. The development of microarrays and allied technologies were direct outgrowths of recombinant DNA technology and can be used to identify and screen for all types of molecular genetic variation affecting genes, pathways and molecules relevant to human genetic disease, including variations of pharmacogenetic importance. Microarray

applications currently span all aspects of molecular biological investigation, mainly in research regarding the analysis of genetic profiles of humans and other targeted organisms. The application of microarrays with bioinformatic technology is on the threshold of contributing substantially to improved diagnosis and therapeutic management of patients in a clinical setting.

ABBREVIATIONS AND ACRONYMS

bp	base pairs
cDNA	Complementary DNA
G6PD	Glucose-6-phosphate Dehydrogenase
MALDI/TOFMS	Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry
mRNA	Messenger RNA
PCR	Polymerase Chain Reaction
RFLP	Restriction Fragment Length Polymorphism
VNTR	Variable Number Tandem Repeat

The large number of lipid classes and great complexity of molecular species present in blood plasma, red cells, platelets and atheromatous lesions requires a combination of analytical techniques for comprehensive analyses, including chemical and enzymatic derivatization of samples. In many instances only partial analyses are required, which can be accomplished by specific analytical techniques. This chapter describes the full spectrum of the methodology ranging from the most basic thin-layer chromatography (TLC) to the detailed mass spectrometric assays. Traditional sample extraction by liquid–liquid partition is time-consuming and involves large volumes of solvents. Liquid–solid extraction using adsorbent cartridges is more economical. At the present time total lipid extracts can be effectively assayed for lipid class content and molecular species composition by flow injection tandem mass spectrometry (MS/MS), while a more detailed analysis of complex lipid mixtures is provided by a combination of liquid chromatography with on-line electrospray mass spectrometry (LC/ESMS). The new techniques permit completion of the analyses in a few hours, where previously several days or weeks may have been required. The soft ionization mass spectrometric techniques have permitted the recognition and detailed analysis of such minor components of blood as the lipid oxidation and glycation products often observed in disease.

1 INTRODUCTION

Phospholipids occur in blood largely in cell membranes and lipoproteins where they provide structural components and serve as reservoirs of signaling molecules. The plasma lipoproteins, red cells and platelets contain complex mixtures of glycerophospholipids and sphingomyelins (SMs). The choline (Cho) and ethanolamine (Etn) glycerophospholipids and SMs constitute the major and the inositol and serine glycerophospholipids the minor components of the blood system. Each glycerophospholipid class consists of molecular species made up of pairs of fatty acids (FAs) of different chain length and degree of unsaturation. In SMs the nitrogenous base, sphingosine is paired with FAs of differing chain length and degree of unsaturation. In the past the molecular species composition of blood glycerophospholipids and SMs has been extensively studied as an analytical challenge. More recently, the recognition of the special role that these molecules play in metabolic regulation provided a more legitimate basis for such efforts. With detailed analyses permitted by new instrumentation have come discoveries of new phospholipid subclasses and molecular species. In the following both new (LC/ESMS) and old (TLC and gas chromatography) analytical methods are reviewed as an aid to modern studies of the role of glycerophospholipids and SMs in cellular signaling and metabolic regulation.

2 GENERAL STRUCTURE AND NOMENCLATURE

The phospholipids are members of a large class of lipids which are characterized by the fact that on complete hydrolysis they all yield, among other products, inorganic phosphate (P_i). The large variety of phospholipid classes and FAs associated with them has led to the introduction of abbreviated nomenclature and short-hand

Encyclopedia of Analytical Chemistry

designation in order to simplify discussion and promote comprehension.[1]

2.1 Glycerophospholipids and Sphingomyelins

The simplest phospholipid is phosphatidic acid (PtdOH, **(1)**), which on hydrolysis yields one equivalent each of glycerol (Gro) and of phosphoric acid (P) and two equivalents of FA, one of which is saturated, the other unsaturated. The P is bound to Gro in ester linkage at the primary *sn*-3-hydroxyl group. In the phosphatides, the P is also bound in ester linkage to one of the following polar head groups: choline (PtdCho, **(2)**), ethanolamine (PtdEtn, **(3)**), L-serine (PtdSer, **(4)**) and inositol (PtdIns, **(5)**). The plasmenyl subclass of phosphatides yields on mild acid hydrolysis one mole each of aliphatic aldehyde, FA, Gro, P and a nitrogen-containing base (Etn or Cho). The aldehyde formed on mild acid hydrolysis of plasmalogens is derived from an aliphatic chain linked to Gro in a vinyl ether linkage. The plasmanyl subclass of the phosphatides on transmethylation yields one mole each of alkylglycerol, FA, Gro and P and a nitrogen-containing base (Etn or Cho). The Etn moiety of PtdEtn may contain a FA in an amide linkage, while the *myo*-inositol residue of the PtdIns glycans may contain a palmitic acid in an ester linkage. The total lipid extracts of platelets may also include phosphatidylglycerol (PtdGro) and cardiolipin **(6)** or diphosphatidylglycerol (Ptd_2Gro) which are characteristic of mitochondria. Each lipid class is made up of numerous molecular species, which contain fatty chains differing in length and degree of unsaturation. The unsaturated and especially the polyunsaturated species may become peroxidized to variable extent depending on the oxidative stress of the tissue and the endogenous protective mechanisms (see below).

(1)

(2)

(3)

(4)

The glycerophospholipids are subject to hydrolysis by phospholipases (Figure 1). Phospholipase A_2 releases the FA (usually unsaturated) from the *sn*-2-position, while phospholipase A_1 releases the FA (usually saturated) from the *sn*-1-position. Phospholipase C releases the *sn*-1,2-diacylglycerol and phospholipase D the PtdOH moiety of the glycerophospholipids. Many of the phospholipases exhibit specificity for the polar head group of the glycerophospholipid.[2]

(5)

(6)

Figure 1 Sites of enzymatic cleavage in a glycerophospholipid. X is Cho, Etn, serine, or inositol headgroup.

The SMs (*N*-acylsphingosine-1-phosphocholines) **(7)** constitute the second largest phospholipid class in plasma lipoproteins and red blood cells. SM contains the amino alcohol sphingosine **(8)** and its homologs. The sphingosine base is esterified to phosphoryl Cho and is involved in an amide linkage to saturated FAs, although some unsaturated species are also present. SMs are relatively resistant to alkaline hydrolysis, which may be taken advantage of during isolation of ceramides **(9)** and SM.

SM is subject to hydrolysis by phospholipase C or sphingomyelinase, which releases the ceramide moiety. Their characterization is usually performed by hydrolysis and separate identification of the FA and long chain base components,[3] but intact ceramides can also be readily determined by gas–liquid chromatography (GLC)[4]

(7)

(8)

(9)

or high-performance liquid chromatography (HPLC),[5] both techniques permitting on-line combination with mass spectrometry (MS) (see below).

2.2 Phosphatidylinositol Phosphates

The *myo*-inositol residue of PtdIns may contain one to four P groups, which may occur as single or multiple isomers. The numbering of inositol phosphate isomers has been discussed and summarized by Parthasarathy and Eisenberg.[6] Structures **(10–14)** are the structures of the PtdIns phosphates and show the abbreviations recommended by International Union of Biochemistry/International Union of Pure and Applied Chemistry.[1] The structures of the PtdIns phosphates are commonly characterized by chromatography of the intact or deacylated molecules using various chromatographic systems and appropriate reference standards. The distribution of the phosphate groups between the fourth and fifth positions of the inositol ring may be determined by the method of Hawkins et al.,[7] which depends on peroxidate oxidation under conditions which restrict oxidation of the Gro moiety.[6,8] Alternatively, the PtdIns phosphates are characterized on the basis of their susceptibility to specific phosphatases and phospholipases using radioactive substrates. Figure 2 indicates the transformations of the polyphosphoinositides under the influence of the phosphatases and kinases.[9] Thus, PtdIns 3-kinase phosphorylates the D3-position of the inositol ring of PtdIns to produce a PtdIns (3)P that is distinct from PtdIns (4)P, the predominant monophosphate from cellular PtdIns.[6] In addition, the PtdIns 3-kinase also phosphorylates PtdIns (4)P and PtdIns (4,5)P_2 to generate two additional phospholipids, PtdIns (3,4)P_2 and PtdIns (3,4,5)P_3, respectively.[10] Four immunologically distinct forms of PtdIns-specific phospholipase C have been identified.[9] All isozymes require Ca^{2+} and degrade PtdIns, phosphatidylinositol phosphate (PtdIns P), and

Figure 2 Phosphatase and kinase-mediated pathways of polyphosphoinositide transformation.[9] The kinase pathways catalyzed by known enzymes are as follows: 1–3, PtdIns 3-K; 4, PtdIns (4)P 5-K; 5, PtdIns (3)P 4-K; and 6, PtdIns 4-K. The kinase pathways not yet proven are as follows: 7, PtdIns (3,4)P_2 5-K; 8, PtdIns (3)P 5-K; and 9, PtdIns (3,5)P_2 4-K. The solid lines indicate known enzymatic activities. The dotted lines indicate hypothetical pathways.

PtdIns P_2, but the type of lipid degraded depends on the reaction conditions.

Figure 3 Structure of glycosyl PtdIns and production of PtdIns lipid fragments: cleavages for a PtdIns-anchored protein containing inositol + hydroxyester-linked palmitic acid, and 1-alkyl-2-acyl-glycerol; only lipid products are shown.[13] Phospholipid fragments may be generated by nitrous acid (HONO) treatment, or by cleavage with GroPIns-specific phospholipase D (GPI-PLD). AcylGro may be generated by enzymatic treatment, using bacterial PtdIns-specific phospholipases C (PI-PLC*, the asterisk indicating that PI-PLC will cleave only GPI structures that are not inositol acylated), or by chemical treatment via acetolysis or aqueous HF dephosphorylation. Alkali treatment removes the ester-linked FAs (including the inositol-linked FA if present), and PI-PLC treatment of the resulting lyso-GPI anchor generates 1-alkylglycerol. AcylGro fragments and free FAs are extracted into hexane, toluene, or chloroform–methanol (2:1, v/v). Phospholipid fragments are extracted into water-saturated 1-butanol.

2.3 Other Phospholipids

Glycated PtdIns constitute a diverse family of lipid molecules found in prokaryotes and eukaryotes. The members of this family are characterized by the sequence Etn-PO_4-Manα1-4GlcNα1-6-*myo*-inositol-1-PO_4-diradylglycerol.[11] These structures are involved in anchoring membrane proteins including the acetylcholine esterase of the human red blood cells. The complete structure of the PtdIns anchor of human red blood cell acetylcholine esterase has been determined and shown to possess a C-terminus of the protein linked via Etn phosphate to a glycan with the conserved backbone sequence Manα 1-2Manα 1-6Manα 1-4GlcNH_2, which in turn is linked to the 6-position of the *myo*-inositol ring of PtdIns.[12] The presence of a palmitate residue on one of the inositol hydroxyls renders the anchor resistant to PtdIns-specific phospholipase C hydrolysis. Figure 3 gives the structure of the glycosyl PtdIns anchors along with the chemical and enzymic cleavage points.[13]

3 ISOLATION

The method of lipid extraction and subsequent work-up of the extract are critical to the outcome of the analysis and the reliability of the data. Both must be executed with care. The blood from volunteers is taken into sterile donation bags containing cytidine diphosphate adenine as preservative (115 mM citrate–NaOH, pH 7.3, 160 mM glucose, 21 mM NaH_2PO_4, 2 mM adenine) (Travenol Labs, Thetford, Norfolk, UK). The analysis of blood lipids involves several discrete steps, some of which can be combined depending on the aims of the analysis. The work-up usually involves a separation of plasma and cells, which is accomplished by centrifugation at 500 *g* for 10 min and washing the cells to remove the buffy coat. The erythrocytes are washed four times in ice-cold 154 mM NaCl–1.5 mM Hepes, pH 7.2, the buffy coat and supernatant being also collected. Residual leukocytes are removed by passing the washed cells through a sterile cotton wool column (Cellselect Leukocyte filter).

Platelets are isolated by collecting the buffy coats and recentrifuging them in buffer or saline.[14] However, Low[15] recommends that prostaglandin E_1 (PGE_1) (2.8 μM) is added to the buffer solution since it prevents platelet activation and increases the yield of [^{32}P]polyphosphoinositide. The platelets are prepared from fresh human blood (60 mL) and suspended in 3 mL of 140 mM NaCl, 5 mM KCl, 0.005 mM $CaCl_2$, 0.1 mM $MgCl_2$, 16.5 mM glucose, 0.1 mg serum albumin mL^{-1}, 15 mM Hepes (pH 7.4), containing 2–6 mCi [^{32}P]P_i (carrier free) for 2 h at 37 °C with occasional gentle shaking.

Prior to lipid extraction the plasma membranes of the red cells can be isolated as the normal or inverted ghosts.[16] Furthermore, differentiation can be made between the glycerophospholipids associated with the inner and outer half of the lipid bilayer of the red cell plasma membrane. This is usually accomplished by differential chemical or enzymatic derivatization.[16] In addition to the transbilayer asymmetry of a phospholipid class, some studies have indicated a nonrandom lateral distribution of phospholipid subclasses. The plasma samples are resolved into the major lipoprotein classes by ultracentrifugation using any one of several methods.[17]

3.1 Liquid-phase Extraction

The lipids of plasma and plasma lipoproteins are usually obtained by extraction with chloroform–methanol, while the lipids of the red cells and platelets may be better isolated by chloroform–isopropanol. Complete extraction of the minor acidic phospholipids from all sources requires the use of acidic solvents. Most tissues require special attention to the physicochemical and biochemical properties of the components to be isolated, as described below.

3.1.1 Neutral Solvents

A conventional chloroform–methanol extraction as recommended by Folch et al.[18] or Bligh and Dyer[19] commonly contains the neutral lipids and weakly acidic phospholipids, which make up the bulk of the lipid phase of plasma lipoproteins.[20] These extracts obtained in the absence of acidic solvents, also contain the alkylacyl and the acid labile alkenylacyl glycerophosphocholine (GroPCho) and glycerophosphoethanolamine (GroPEtn). Such extracts have been used for normal phase liquid chromatography/mass spectrometry (LC/MS) with on-line electrospray.[21–23] For complete extraction of the acidic lipids a two-step procedure is necessary (see section 3.1.2).

The extraction of lipids from red cells and platelets can also be performed with the chloroform–methanol routines, especially if the cell membranes are prepared first. However, these methods yield pigmented lipid extracts when applied to whole red cells. Rose and Oaklander[24] have suggested the use of chloroform–isopropanol (7 : 11, v/v) for the extraction of human erythrocytes. This method minimizes the extraction of pigments and has been widely applied. Nakamura et al.[25] have recently provided details for an improved protocol. Briefly, distilled water (1 mL) is added to the red cell pellets and incubated for 15 min, then propan-2-ol (11 mL) is added and vortex mixed thoroughly. The mixture is incubated for 1 h with frequent vortex mixing, which is followed by the addition of chloroform (7 mL). After further vortexing, the mixture is allowed to stand for 1 h, then centrifuged (500 *g*) for 30 min and the supernatant evaporated to dryness under nitrogen. A similar routine may be applied to platelet lipid extraction, but acidic phospholipids and PtdIns phosphates are not adequately recovered without acidification (see section 3.1.2).

Total lipid extracts from atherosclerotic plaques are obtained by Folch extraction of the homogenate of the total tissue.[26,27] However, acidification increases the recovery of the acidic and lysophospholipids (see section 3.1.2). Extraction of largely neutral atheroma lipids has been obtained by Suarna et al.[28] with a mixture of cold methanol (2 mL) and hexane (10 mL) in the presence of lipid-soluble external standards and butylated hydroxytoluene (BHT, 100 μmol L^{-1}) and ethylenediamine tetraacetic acid (EDTA, 1.0 mmol L^{-1}). On the basis of careful investigation, a 5-min homogenization period under these conditions was found to be optimal for the efficient extraction of neutral lipids without substantial destruction of antioxidants.

The neutral phospholipid extracts also recover the glycated PtdEtn and glycated PtdSer,[22] which may be stabilized by reduction with sodium borohydride, and the peroxides. The hydroperoxides may be reduced to the hydroxides by means of cyanoborohydride before further analysis (see section 3.1.2).

3.1.2 Acidic Solvents

A complete extraction of the acidic phospholipids, e.g. lysophospholipids, platelet activating factor (PAF) and other minor acidic phospholipids, PtdSer, PtdIns, and PtdIns phosphates, requires acidification of the extraction solvents. The more strongly acidic phospholipids are isolated by re-extracting the aqueous phase with two volumes of chloroform–methanol–12 M HCl (2 : 1 : 0.012, v/v/v) after an initial removal of the neutral and less acidic phospholipids by chloroform–methanol (2 : 1, v/v) as described above or by diethylamino ethyl (DEAE)-Sephadex columns.[29,30] The organic layer obtained from the acidic chloroform–methanol extract is subsequently neutralized with one drop of 4 M ammonium hydroxide and combined with the first organic extract. For isolation of PtdIns phosphates,[8] samples of an erythrocyte suspension (5 mL, containing 1 mL of packed cells) are lysed in ice-cold 20 mM Tris–HCl–2 mM EDTA, pH 7.2 (70 mL; lysis buffer). This procedure preserves the concentrations of PtdIns-Ps in vivo.[8,31] The membranes are sedimented (15 000 *g* × 20 min) and washed in lysis buffer until white (usually four to six washes). Lipids are extracted from the membranes (final volume, 2 mL) by the addition of chloroform–methanol–HCl (20 : 40 : 1, v/v/v; 7.5 mL). After 20 min at room temperature, this solvent mixture is partitioned by addition of 0.1 M HCl (2.5 mL) and chloroform (2.5 mL). The resulting lower phase is taken, dried in vacuo, and the lipids are dissolved in chloroform.

According to Low[15] platelet lipids (platelets prepared from 60 mL of fresh blood) are extracted with 11.25 mL of chloroform–methanol–HCl (50 : 100 : 1.3, v/v/v) for 30 min at 25 °C. Chloroform (3.75 mL) and 0.1 M HCl (3.75 mL) are then added to separate the phases. The lower phase is washed twice with 5 mL of methanol, 4.5 mL of 2 M NaCl, 0.5 mL of 100 mM EDTA–NaOH (pH 7.4) and then evaporated to dryness in a clean tube

with approximately 1.5 μmol of acid-washed methanol-precipitated bovine brain phosphoinositides (material prepared as above) to act as carrier. The extract is finally redissolved in 0.5 mL of solvent A (chloroform–methanol–water, 20 : 9 : 1, v/v/v) and applied at a flow rate of 1 mL min^{-1} to a 4.5 mm × 250 mm amino normal-phase column equilibrated with solvent A. The column is eluted with 5 mL of solvent A, a 2.25 mL linear gradient from 100% solvent A to 100% solvent B (solvent A containing 0.6 M ammonium acetate). Fractions (1 mL) are collected and radioactivity determined by liquid scintillation counting. Average recovery of applied radioactivity is approximately 70% (see below).

The PtdIns anchors of proteins in neutral detergents, such as Triton X-100 or Nonidet P-40, can be recovered by exhaustive proteolysis.[32] After vortexing and centrifugation the toluene phases are removed, leaving behind the interface. The PtdIns peptides remain in the aqueous phase and can be recovered by rotary evaporation to remove residual solvents and freeze-dried to remove residual ammonium acetate. The PtdIns anchors can be released by enzymatic or chemical degradation. The washed extracts containing the free PtdIns glycan are purified by TLC on Si-60 plates (Merck, Darmstadt, Germany) using either chloroform–methanol–water (4 : 4 : 1, v/v/v; solvent A) or chloroform–methanol–concentrated acetic acid–water (25 : 15 : 4 : 2, v/v/v/v; solvent B). The metabolically labelled glycolipids (HPLC purified or within the glycolipid mixture) are identified as PtdIns by specific enzymatic and chemical treatments including PtdIns-specific phospholipase, PtdIns-specific phospholipase D and HNO_2 deamination, as described elsewhere.[33]

3.2 Solid-phase Extraction

Solid-phase extraction (SPE) may be carried out using normal- and reversed-phase adsorbents, affinity and ion-exchange columns. All of these methods have been employed with various degrees of success for the isolation of individual or mixed lipid classes. However, only a few actual applications have been reported to plasma or blood cell lipids.[34]

3.2.1 Normal-phase Columns

Hamilton and Comai[35] have described a method for the isolation and separation of neutral lipid, free FA and polar lipid classes using small (600 mg) prepacked silica Sep-Pak cartridges. Serum lipids from Bligh and Dyer extraction equivalent to 100 μL of human serum are evaporated to dryness under nitrogen, dissolved in 2.0 mL of hexane–methyl *tert*-butyl ether (MTBE), 200 : 3 and applied to the Sep-Pak column. Combinations of hexane and MTBE are used to progressively elute cholesteryl ester first then triglyceride from the column. After column acidification, FAs are eluted followed by cholesterol. Polar lipids are eluted from the column using combinations of MTBE, methanol and ammonium acetate. PtdEtn and PtdIns eluted together, whereas PtdCho, SM and LysoPtdCho are eluted as a second fraction. Recoveries of each phospholipid are greater than 98%.

Janero and Burghardt[34] have described an optimized procedure for selectively removing blood neutral lipids and noncholine-containing phospholipids from complex lipid mixtures and thereby obtaining a Cho phospholipid fraction markedly enriched in bioactive PAF. From a commercial Sep-Pak cartridge (600 mg silica, Waters, Milford, MA) PAF could be quantitatively eluted along with other Cho phospholipids and free neutral lipid in 10 mL methanol–chloroform–water (2 : 1 : 0.8, v/v/v). With the exception of some PtdSer, negligible noncholine-containing phosphoglycerides remained on the cartridge. The lipids in the PAF-enriched fraction could immediately be re-extracted into chloroform by adding 4 mL water and 3 mL chloroform to the fraction. Figure 4 shows a normal-phase HPLC elution profile obtained for the PAF-enriched fraction using propanol–toluene–acetic acid–water (93 : 110 : 15 : 15, v/v/v/v) as the eluting solvent. A mixture of seven radiolabeled phospholipids (60 000 cpm each) made up of PtdEtn, PtdOH, PtdSer, PtdCho, SM, PAF and lysoPtdCho was subjected to the SPE procedure. The HPLC eluate was collected at 1 min intervals over a 50 min run counted by scintillation spectrometry.

A type of SPE and preliminary segregation of phospholipid classes from a total lipid extract is provided by normal-phase HPLC employed as a method of admission of phospholipids to a mass spectrometer for lipid class and molecular species determination.[22,23,36] A gradient solvent system originally described by Becart et al.[37] has proven to be highly compatible with electrospray ionization (see section 4).

As noted above, none of these methods is effective in separating PtdIns phosphates in pure form from crude tissue extracts. Therefore, the lipid extracts are processed using several chromatographic steps. Singh[38] has described the extraction and analysis of PtdIns, PtdIns (4)P and PtdIns (4,5)P_2 using a Sep-Pak cartridge to provide both mass and radiolabeling. Although this method has not been specifically applied for the isolation of PtdIns phosphates from blood lipids, it is included here because of its apparent potential. Thus, a total lipid extract of rat brain synaptosomes and microvessels is first prepared according to Folch et al.[18] and fraction 1 is collected and further extracted to separate phospholipids and glycolipids as described by Dugan et al.[39] The

Figure 4 SPE on silica Sep-Pak cartridges as an aid to PAF isolation by HPLC.[34] A mixture of seven radiolabeled phospholipids (60 000 cpm each) was subjected to the SPE procedure. Peak identification is shown. The PAF-enriched fraction was subjected to HPLC with solvent comprising of propanol–toluene–acetic acid–water (93 : 110 : 15 : 15, v/v/v/v) at a flow rate of 2 mL min^{-1} on a Zorbax™ 5 µ silica column (250 × 4.6 mm ID). The HPLC eluate was collected at 1-min intervals over a 50-min run and counted by liquid scintillation spectrometry. The elution profile given is representative of three independent runs. Peak identities were established by the HPLC elution volume and retention time of each radiolabeled lipid standard chromatographed separately. (Reproduced with permission from Janero and Burghardt.[34])

phospholipid fraction was resolved by DEAE-cellulose chromatography (separation sequence 4) as described by Rouser et al.[40] to purify further the inositol lipids. The purified extract is transferred to Sep-Pak cartridge. Various inositol lipids are eluted from the column with a linear gradient of ammonium acetate and water from 0.5% of ammonium acetate (200 mM) and 99.5% of water to 75% of ammonium acetate and 25% of water in 60 min at a flow rate of 0.5 mL min^{-1}. The column eluate for 120 min is collected in 1-mL fractions. Different peaks were identified using PtdIns, PtdIns (4)P and PtdIns (4,5)P_2 as standards. The fractions containing individual inositol lipids were pooled and analyzed for purity by HPLC as described by Van Kessel et al.[41] The phospholipids were detected at 206 nm using a diode array detector programmed to scan from 200 to 350 mm.

Atheroma lipids are isolated from the total chloroform–methanol lipid extracts by TLC and the neutral lipids, PtdCho, SM and LysoPtdCho resolved using chloroform–methanol–water–acetic acid (65 : 25 : 4 : 1, v/v/v/v) as the solvent system.[42]

3.2.2 Reversed-phase Columns

Kaluzny et al.[43] have used aminopropyl bonded phase (Bond-Elut, Analytichem International, Harbor City, CA) for the separation of complex lipids into individual classes in high yield and purity. The method was developed with up to 10 standard lipid classes. It has proven to be rapid and simple for the separation of serum neutral and phospholipids.[44] Figlewicz et al.[45] have shown that the Bond-Elut cartridges can be used to take up lipids from aqueous incubation mixtures. The procedure was simpler than Folch extraction. According to Salari,[46] however, other C_{18}-cartridges (Waters, Milford, MA) did not retain phospholipids significantly when plasma samples diluted with 2 volumes of phosphate-buffered saline acidified to pH 5 with HCl were passed through the adsorbent.

Kim and Salem, Jr[47] have shown that reversed-phase HPLC columns can be effectively employed for a preliminary resolution of phospholipid classes and

molecular species in combination with electrospray mass spectrometry (ESMS) (see below).

3.2.3 Ion-exchange Columns

DEAE-cellulose columns have been extensively utilized for the isolation of particular groups of complex lipids.[40,48] The separation involves partly ionic interactions between the packing material and the polar head groups of complex lipids, and partly adsorption effects with the polar regions of the molecules. According to Christie[48] PtdCho is eluted with chloroform–methanol (9 : 1, v/v), PtdEtn with chloroform–methanol (1 : 1, v/v), PtdSer with glacial acetic acid, and PtdIns with chloroform–methanol (4 : 1, v/v) made 0.05 M with NH_4OAc and 0.56% with respect to NH_4OH. Residual salts are removed from the last fraction by rapid extraction and partition using 0.9% NaCl. Clear-cut fractions are obtained with virtually no cross-contamination using sequential elution from the same DEAE column.

Salari[46] has demonstrated that the Amberlite resins were selective for removal of phospholipids by direct adsorption from plasma. A recovery of greater than 85% was obtained for PtdCho, PtdIns, and PtdSer when XAD-7 or XAD-8 were used as adsorbents. A recovery of about 90% for PtdEtn was obtained when XAD-2 or XAD-4 were used as adsorbents. A solvent mixture of isopropanol–acetonitrile (1 : 1, v/v) was found to be the most effective eluent for removal of phospholipids from the Amberlite polymeric resins. Prior to this time, Salari[49] had demonstrated greater than 95% recovery of the PAF from plasma and incubation media using Amberlite XAD-2 (Serva Feinbiochemica, Heidelberg, Germany) as retaining medium. For this purpose fresh plasma (heparin anticoagulant) is diluted with 2 volumes of Tyrod's buffer and the mixture is acidified to pH 5 with 1 M HCl. The acidified solution is passed through an XAD-2 (1 g dry resin in 10 mL glass syringe) column, which has been previously sequentially washed with 20 mL acetonitrile, 10 mL methanol and 40 mL distilled water. The column is allowed to run at a flow rate of approximately 0.5 mL min^{-1}. Plasma eluates are collected for determination of unretained lipids. The columns are washed with 3×5 mL of distilled water and each individual 5 mL of water eluate is collected. The columns are then eluted with 15 mL methanol at a flow rate of approximately 1.5 mL min^{-1}. Under these conditions 96% of added radioactive 1-*O*-alkyl-2-acetyl-*sn*-glycerol-3-phosphocholine is recovered in the methanol fraction.

Dionex-anion-exchange HPLC has been used for the separation of glucose oligomer standards and PtdIns glycan fragments.[13] The analysis is performed on an HPIC AS6 column (Dionex Corporation, Sunnyvale, CA) using a gradient system. The gradient began with 100% solvent A (0.1 M NaOH), 0% solvent B (0.5 M CH_3COONa, 0.1 NaOH) up to 3 min after sample injection, followed by a linear change to 55% solvent A, 45% solvent B at 33 min, then 0% solvent A, 100% solvent B at 38 min. The flow rate is 1 mL min^{-1}. The glucose oligomer standards and carriers are prepared by partial acid hydrolysis of dextran. Glycosyl PtdIns glycans prepared by nitrous acid treatment of nonprotein-linked glycosyl PtdIns can be analyzed by conventional anion-exchange chromatography to determine their net negative charge.[13] The analysis is conveniently performed with a Mono Q column (HR 5/5, bed size 5×50 mm) and a gradient fast protein liquid chromatography (FPLC) system (Pharmacia, Stockholm).

3.2.4 Affinity Columns

The antibiotic neomycin exhibits a specific affinity for the polyphosphoinositides. The other weakly acidic phospholipids are retained because neomycin also acts as a weak anion exchanger. For the extraction and purification of PtdIns P and PtdIns P_2, Palmer[50] and Letcher et al.[51] recommend the immobilized neomycin columns originally described by Schacht.[52] All anionic lipids present in chloroform–methanol extracts, which have been washed first with acid and then with neutral salts solution are adsorbed. PtdSer and PtdOH are eluted with chloroform–methanol–formic acid mixtures. PtdIns and cardiolipin are eluted sequentially with very low concentrations of ammonium formate in chloroform–methanol–water. All three PtdIns Ps are isolated from washed chloroform–methanol–KCl extracts of rat brain. PtdIns P and PtdIns P_2 are eluted in turn by higher salt concentrations (0.4–1.0 M). Similar methods have been used to isolate the PtdInss from human plasma lipoproteins.[50] Letcher et al.[51] have found that simply using the eluants described by Palmer[50] results in cross-contamination between the three principal inositol lipids, and to prepare really pure PtdIns P, a stepwise elution has to be carried out from 200 mM to 500 mM in 100 mM steps and then taking only the PtdIns P revealed to be pure by TLC analysis.[53]

3.3 Derivatization and Preliminary Segregation

Although combinations of HPLC and MS now allow the detection and quantification of many phospholipid classes and molecular species, there remains a frequent need for a preliminary resolution of the phospholipid mixtures.[54,55] Both molecular subclasses and molecular species of various phospholipids are more readily identified by MS following a preliminary chromatographic resolution and purification with or without derivatization. Preparation of derivatives usually renders the lipid molecules less

polar or endows them with ultraviolet (UV) absorbing or fluorescent properties. The derivatization can be effectively combined with SPE using normal-phase cartridges or TLC (see above).

3.3.1 Enzymatic

The polar headgroups of glycerophospholipids and SMs, which cause peak tailing and interfere with chromatographic resolution of molecular species, may be removed by hydrolysis with phospholipase C and the released diacylglycerols and ceramides subjected to trimethylsilylation or *tert*-butyldimethylsilylation to obtain derivatives with excellent gas chromatographic properties and characteristic mass spectra. *tert*-Butyldimethylsilyl (TBDMS) ethers of diacylglycerols are prepared by reaction with a solution of *tert*-butyldimethylchlorosilane–imidazole (1 : 2.5, mol/mol, diacylglycerol–reagent) in dimethylformamide at 80 °C for 20 min.[56] The mixture is extracted with chloroform–methanol (2 : 1, v/v) and washed with water. The trimethylsilyl (TMS) ethers are prepared by reacting the diradylglycerols with a premixed solution of pyridine–hexamethyldisilazane–trimethylchlorosilane (12 : 5 : 2, v/v/v) for 30 min at room temperature[57] or by reaction with a solution of pyridine–bis(trimethylsilyl)-trifluoroacetamide–trimethylchlorosilane (50 : 49 : 1, v/v/v), which yields volatile byproducts.[58] The reagents are evaporated under nitrogen and the products dissolved in 2 mL of petroleum ether (b.p. 30–60 °C). Derivatization of the diradylglycerols immediately after phospholipase C digestion is needed to prevent isomerization during the subsequent chromatographic analyses. The separation of the TMS ethers by normal-phase HPLC yields the alkylacyl, alkenylacyl and diacyl subclasses of the Cho and Etn glycerophospholipids. Attempts to resolve these derivatives by TLC leads to significant breakdown of the TMS ethers. Figure 5(a) shows the separation of alkenylacyl, alkylacyl and diacyl subclasses of the diradyl GroPEtn moieties of the red cells.[59] A similar separation of the diradylglycerol moieties of red cell PtdCho gave much smaller but readily detectable fractions for the ether-linked species. These separations are performed with the TMS ethers of the diradylglycerols. Based on GLC quantification the red cell diradyl GroPEtn contained 48.8% diacyl, 47.8% alkenylacyl and 3.4% alkylacyl, whereas the diradyl GroPCho contained 93.0% diacyl, 4.6% alkylacyl and 2.5% alkenylacylglycerol subclasses. The diradyl GroPIns is 100% diacyl. The detailed FA composition of the various diradylglycerol fractions derived from them is discussed below under molecular species. Figure 5(b) shows the normal-phase separation of alkenylacyl, alkylacyl and diacylglycerol moieties of human plasma diradyl GroPEtn.[60] Although the ether-linked glycerophospholipid content is not measured in the individual lipoprotein classes, it has been observed that each lipoprotein contained at least some of this lipid class. The plasma diradyl GroPEtn consisted of 71.8% alkenylacyl, 19.9% diacyl and 8.3% alkylacyl, whereas the diradyl GroPCho contained 93% diacyl, 3.4% alkylacyl and 3.6% alkenylacylglycerol. The HPLC procedure was clearly superior to the TLC method used previously,

Figure 5 Normal-phase HPLC separation of alkenylacyl, alkylacyl and diacylglycerol moieties of (a) human red blood cell diradyl GroPEtn[59] and (b) human plasma diradyl GroPEtn.[60] Peak identification is given. HPLC conditions: column, Supelcosil LC-Si (5 m) 250 × 4.6 mm ID; solvent, hexane–isopropanol (99.7 : 0.3, v/v), 1 mL min^{-1}; temperature, 30 °C, isothermal. Sample: diradylglycerol TMS ethers. (Reproduced with permission from Myher et al.[59,60])

especially with respect to the resolution of the alkylacyl and diacylglycerol fractions. There is also a partial separation of the molecular species within each diradylglycerol class. The detailed FA composition of the various diradylglycerol fractions derived from them is discussed below under molecular species. Phospholipase C treatment of SM results in release of the ceramide moieties, which also can be converted into the silyl ethers for GLC.[59,60] Phospholipase C dephosphorylation of plasma total lipids has been extensively utilized for a preliminary resolution and quantification of plasma PtdCho, lysoPtdCho and SM,[20] which have yielded estimates comparable to those obtained by combined TLC separation and phosphorus analysis.[61]

For HPLC resolution the diradylglycerols released from the glycerophospholipids by phospholipase C may be converted into benzoates,[62] pentafluorobenzoates,[63] or other UV absorbing or fluorescent derivatives. The diradylglycerols are converted into the naphthylethyl urethanes for resolution as the diastereomers on normal-phase HPLC[64] or into dinitrophenylurethanes for separation of enantiomers on a chiral phase column.[65]

Other useful derivatives for the identification and/or resolution of glycerophospholipids may be prepared by phospholipase D, which releases the PtdOH moiety along with the nitrogenous base or inositol moiety. The PtdOH may be methylated[66] and the lysoglycerophospholipids acetylated[66] for further chromatographic and mass spectrometric characterization.

The positional distribution of FAs in the glycerophospholipids is determined by hydrolysis with phospholipase A_2 (*Crotalus adamanteus*, Sigma Chemical Co.). For this purpose a portion of the purified phospholipid (<0.5 mg) is vortexed for 3 h at 37 °C in a mixture made up of 2 mL of Tris buffer (17.5 mM) trishydroxymethylaminomethane, adjusted to pH 7.3 with dilute HCl, 1.0 mM $CaCl_2$, 2 mL diethyl ether, 50 μg BHT and 50 units of phospholipase A_2.[58] After acidification with one drop of concentrated HCl, the mixture is extracted first with five parts chloroform–methanol (2:1, v/v), then with two parts chloroform–methanol (4:1, v/v). The extract is then resolved by TLC on silica gel H plate (20 × 20 cm). The plates are first developed to a height of 11 cm using chloroform–methanol–acetic acid–water (100:35:10:3, v/v/v/v), dried under nitrogen gas for 10 min and then developed to a height of 15 cm using heptane–isopropyl ether–acetic acid (60:40:4, v/v/v). Alkylglycerols are not determined by this procedure and must be analyzed separately.[67] In order to measure the extent of hydrolysis, one set of the tubes is quantified by GLC after addition of 50 μg of methyl heptadecanoate as internal standard. The residual glycerophospholipids usually correspond to approximately 0.5% of total.

The sidedness of the phospholipid composition of the red cell membrane can also be determined by phospholipase A_2. Using bee venom or *Naja naja naja*, Wilson et al.[68] demonstrated that hyperglycemia induces loss of asymmetry due to increased passive phospholipid flip-flop caused by a secondary effect of hyperglycemia, such as phospholipid peroxidation, or nonenzymatic protein glycosylation.

3.3.2 Chemical

Alternatively, PtdEtn and PtdSer may be subjected to N-derivatization to improve their chromatographic and mass spectrometric properties.[47] It permits reversed-phase chromatography with UV and mass spectrometric detection. Of special interest is the preparation of the trinitrobenzene sulfonate derivatives of the aminophospholipids from intact red cell ghosts, which have been utilized in studies of the molecular species distribution of aminophospholipids between the inner and outer halves of the phospholipid bilayer of the red blood cell.[69,70] Since this approach is not applicable to the Cho-containing glycerophospholipids, chemical methods have been sought for removing the polar head groups. Dephosphorylation of glycerophospholipids comparable to that of phospholipase C hydrolysis may be obtained by acetolysis, which, however, leads to partial isomerization of the released diacylglycerols and destruction of plasmalogens.[58] Acetolysis may provide a desirable choice for chemical degradation of PtdIns glycans, despite isomerization of the diradylglycerol moieties.[12]

Acid vapor decomposition is a crude but effective method for the removal of plasmalogens from glycerophospholipid mixtures.[71,72] Alkaline destruction of the glycerophospholipids is frequently used to purify the SM and its metabolites, which are relatively resistant to alkaline hydrolysis, and can be subjected to mild alkaline hydrolysis in 0.6 N NaOH in methanol, for 1 h at 37 °C to destroy the glycerophospholipids.[73] The phases are separated by adding 1 mL each of chloroform and water, and the organic phase is dried through an anhydrous sodium sulfate column. The alkali-stable lipids are separated on high-performance thin-layer chromatography (HPTLC) plates using chloroform–methanol–acetic acid–water (25:15:4:2, v/v/v/v) as the developing solvent. Lipids are visualized under iodine. For further analysis, ceramide, SM and other alkali-stable compounds are scraped off the plate and the lipid material is eluted from the silica gel with chloroform–methanol (2:1, v/v).

In other instances the hydrophobic moieties of the glycerophospholipids have been removed by deacylation and the water-soluble residues analyzed by chromatography. The deacylation procedure may be performed as follows.[74] Labeled PtdIns phosphates that have been

produced as described above and extracted in chloroform are washed with an equal volume of methanol–0.1 M EDTA (1 : 0.9, v/v) and placed in a glass, screw-capped scintillation vial (20 mL capacity), and then dried under a stream of nitrogen gas. In a fume cupboard, 1.8 mL of methylamine reagent (42.8% of 25% (v/v) methylamine in water, 45.7% (v/v) methanol, 11.5% (v/v) 1-butanol, stored at 4 °C) are added to dissolve and hydrolyze the dried lipids. The tightly capped vial is incubated at 53 °C with constant shaking for 50 min. After this incubation, the contents of the vial are cooled to room temperature, transferred to a 2.0 mL microfuge tube, and dried in vacuo. The dried samples are resuspended in 2.0 mL of distilled, deionized water, transferred to a glass test tube, and extracted two times with an equal volume of 1-butanol–petroleum ether–ethyl formate (20 : 4 : 1, v/v/v) to remove fatty acyl groups. After these extractions, the lower, aqueous phase is dried in vacuo by roto-evaporation and stored at −70 °C until analysis by HPLC. The deacylation may be conveniently performed following TLC purification. The region of the TLC plate that contains a particular phospholipid is carefully excised, placed in a glass screw-capped scintillation vial, and treated with methylamine reagent exactly as described above. The deacylation residues of polyphosphoinositides are resolved by HPLC using a high resolution 5 μm Partisphere SAX column (Whatman) and a shallow discontinuous salt gradient. The HPLC column is equilibrated with water prior to sample loading and is eluted with a discontinuous gradient up to 1 M $(NH_4)_2HPO_4 \cdot H_2PO_4$ (pH 3.8) at a flow rate of 1 mL min^{-1}. The gradient is established from 0 to 1 M of the phosphate buffer over 15 min. Kucera and Rittenhouse[75] have employed a similar HPLC column along with a similar buffer gradient for the separation of GroPIns polyphosphates derived from human platelets.

The methyl esters of phospholipids are prepared by reaction with 6% H_2SO_4 in methanol.[58] The methyl esters are extracted with hexane. The linked FAs of the ceramides are converted into their methyl esters by treating an aliquot of the sample (about 50 μg) with 0.5 N methanolic HCl (80 °C, 20 h) and extracting the FA methyl esters into hexane. Aliquots of the resolved diradylglycerol TMS ethers are converted into the FA methyl esters and dimethylacetals by a 2 h reaction at 80 °C with freshly prepared methanol–sulfuric acid (94 : 6, v/v). Alkylglycerol TMS ethers are converted into the diacetates with acetic anhydride–pyridine (1 : 1, v/v) after transmethylation of the alkylacylglycerol TMS ether with 1 N sodium methoxide in methanol–toluene (3 : 2, v/v) for 15 min at 20 °C. Following methanolysis, the mixture is neutralized with 1% acetic acid in hexane and extracted by adding 200 μL chloroform, 0.5 mL water and 50 μL 3 M aqueous ammonia. The organic phase is washed with 250 μL water and then dried by passing it through a small column of anhydrous sodium sulfate. After drying under nitrogen, the sample is acetylated for 0.5 h at 80 °C with 75 μL acetic anhydride–pyridine (1 : 1, v/v). The reagent is removed by evaporation under nitrogen and the products purified by HPLC.

4 RESOLUTION OF COMMON PHOSPHOLIPIDS

LC/MS and MS/MS with electrospray now offer an analytical method clearly superior in resolution, speed and overall convenience to either HPLC or TLC/GLC methods for the analysis of many phospholipid classes and molecular species. However, the older chromatographic methods are still required for the isolation and purification of standards and occasionally for verification of the mass spectrometric results obtained on the more complex lipid mixtures. A brief description of the principles of the various methods and the merits of each for specific applications is therefore included here.

4.1 Principles of Methodology

4.1.1 Thin-layer, Liquid and Gas–Liquid Chromatography

TLC is the simplest and most effective technique for the separation of phospholipids. The separation is based on the differential migration of the various phospholipid classes on thin layers of adsorbent subjected to continuous flow of appropriate organic solvents. The resolved components are readily located by spraying the plate with fluorescent dyes and viewing it under UV light. The adsorbent (usually silica gel) can be scraped off the plate and extracted with organic solvents to recover the purified compounds. Normal-phase HPLC resolves the phospholipid classes on an adsorbent column usually employing a continuous flow of solvent gradient, although isocratic separations are also practiced. Reversed-phase HPLC resolves both lipid classes and molecular species of phospholipids on a hydrophobic column (usually a silanized adsorbent). The separation is based on both adsorptive and partition properties of the phospholipid molecules and is best performed following a preliminary resolution of the lipid classes by TLC or normal-phase HPLC. HPLC requires a special effluent monitor, such as light scattering or a flame ionization detector, because most lipid classes do not absorb UV light or possess fluorescence unless appropriately derivatized. The resolved components are retrieved by a fraction collector. Modern HPLC systems are fully automated and computer controlled. Gas chromatography is the most effective procedure for

the analysis of the FA, diacylglycerol and ceramide moieties of the phospholipids. Modern gas chromatographs equipped with polar capillary columns up to 100 m in length provide complete resolution and quantification of FA methyl esters ranging from butyric to docosahexaenoic acids. Polar capillary columns up to 15 m in length and high thermal stability provide complete resolution of the molecular species of the diacylglycerol and ceramide moieties of phospholipids as the TMS ether derivatives. In all instances highly sensitive detection and accurate quantification is obtained by the flame ionization detector, which is a standard part of the modern gas chromatographs.

4.1.2 Liquid Chromatography with On-line Electrospray Mass Spectrometry

ESMS is a relatively new method of soft ionization of phospholipid molecules. In ESMS, ions dissolved in a suitable solvent are charged and droplets are formed at atmospheric pressure and room temperature by electrostatic nebulization. The solvent is evaporated by a curtain of gas until only charged solute remains, which is subsequently drawn into the low vacuum of a mass analyzer. HPLC with on-line ESMS (LC/ESMS) is an ideal combination of chromatographic separation with mass spectrometric identification and quantification of phospholipid classes and molecular species. The ions are characterized by their retention time and the mass/charge (m/z) ratio. Phospholipids usually exhibit a charge of 1. Normal-phase HPLC can be used to resolve the lipid classes and to admit them via the column effluent to the ionization chamber. Likewise, reversed-phase HPLC can be used to resolve molecular species of phospholipid classes and to admit them to the ESMS ionization chamber. In the positive ion mode only the Cho-containing phospholipids are effectively determined, while in the negative ion mode only the acidic phospholipids appear, although the chloride adducts of the Cho-containing phospholipids may also be seen. The ions appearing in the mass spectrometer can be subject to collision-induced dissociation (CID) to produce daughter ions as a further aid to identification and quantification of molecular species (see section 4.3). A pseudo MS/MS effect may be achieved by conducting the LC/ESMS analysis at two different capillary exit voltages. At a low voltage only molecular ions are obtained, while at elevated voltage the molecular ions are subject to CID. Provided the chromatographic peaks have been fully resolved LC/ES/CID/MS yields structural information very much like conventional MS/MS. LC/ES/CID/MS has the advantage of up to 10 times greater sensitivity than MS/MS.[21]

4.1.3 Flow Mass Spectrometry/Mass Spectrometry

In MS/MS, precursor ions are selected with the first of three quadrupoles (Q1) for CID with argon in the second quadrupole (Q2). The third quadrupole (Q3) is scanned with a mass step of 0.02 Da and 1 ms per step. Parent ion transmission is maximized by reducing the resolution of Q1 to transmit a 2 to 3 m/z window about the selected parent ion, and Q3 resolution is adjusted to approximately 50% valley between peaks 3 Da apart.[55] Since the MS/MS approach provides nearly all the information necessary for identification of common phospholipid classes and molecular species, several authors have recommended the replacement of the chromatographic step with a simple flow injection.

Furthermore, the flow MS/MS methods can be employed with total lipid extracts thus eliminating the need for time-consuming and labor-intensive preliminary segregation and derivatization of the phospholipid classes in biological samples.[55,72,76] As a result, lipid class and molecular species analyses can be completed within a few hours instead of the many weeks and months necessary for the combined TLC, HPLC and GLC in the past.

The elimination of the laborious work-up of the samples and the continued exposure to air and active surfaces has led to the recovery of greatly increased proportions of the polyunsaturated and more polar lipid classes and molecular species using the LC/MS and MS/MS approach. A comparison of the MS/MS results with the results of reversed-phase HPLC and capillary GLC obtained with the monobenzoate derivatives of the diradylglycerols derived by phospholipase C hydrolysis of the diradylglycerophosphates has led to the discovery of marked quantitative differences although the qualitative results have been the same between the two methods.[76] The quantitative differences in these techniques are due to the fact that reverse-phase HPLC cannot be utilized to accurately quantitate minor constituents (1–3% of total) and that peaks which are thought to represent single molecular species actually contain multiple different molecular species. Large errors in molecular species analysis of Cho glycerophospholipids by reverse-phase HPLC are attributed to the coelution of multiple molecular species (e.g. 18 : 0–18 : 2 and 18 : 1–18 : 1) with 16 : 0–18 : 1 which are subsequently independently documented by gas chromatographic analysis of column effluents. Furthermore, ESMS yielded greatly increased estimates of the plasmenylEtn molecular species containing arachidonate, which had been previously underestimated due to silicic acid catalyzed hydrolysis of the vinyl ether linkage utilizing conventional chromatographic procedures. Similar observations have been made by comparing the LC/MS and TLC/GLC results for the molecular species of glycerophospholipids of plasma and red cells, with the largest discrepancies being found between the estimates of the

more unsaturated long chain species. Both peroxidation and incomplete recoveries of the longer chain molecular species from the polar capillary columns have suggested a reasonable explanation for the quantitative difference. The success of the mass spectrometric analyses can be attributed directly to the development of the mild ionization techniques, such as electrospray and atmospheric pressure ionization, which, in the initial ionization mode, yield largely the molecular ions with a minimum of fragmentation.

4.1.4 Other Methods

Another method potentially applicable to the rapid determination of the lipid classes in plasma, red cells and platelets is nuclear magnetic resonance (NMR) spectroscopy. NMR spectra arise when a powerful external magnetic field is applied to the nucleus and is made to oscillate between different quantized energy levels at specific radiofrequencies. Very small changes in absorbed energy can be detected, amplified and displayed on a chart. The trace obtained of the variation in the intensity of the resonance signal with increasing applied magnetic field is the NMR spectrum. In organic compounds, the isotope of hydrogen (^{1}H) and to a lesser extent the isotope of carbon (^{13}C) exhibit this phenomenon, although at markedly different sensitivities. In the phospholipids phosphorus (^{31}P) exhibits this phenomenon and ^{31}P-NMR has been widely used for phospholipid quantification, although no specific applications to blood plasma or the formed elements have been reported.[77] A solution of phospholipids is treated with Cs-EDTA to destroy the vesicles and improve band width. After this treatment the ^{31}P-NMR spectrum shows very narrow lines with very good dispersion, so that in most cases phospholipids give signals that are separated from each other. The whole liquid is put into the NMR tube, the lower phase containing the phospholipids and the upper phase containing the waste. The molar amount of phospholipid is calculated based on the fact that the ratio of two signal integrals is equal to the ratio of the corresponding molar amounts, that of the internal standard being known. The signal-to-noise ratio depends on the number of accumulated pulses. A minimum of about 250 pulses are sufficient for routine analysis using a 400-MHz instrument. Approximately 15 to 20 mg phospholipid are required in routine analyses, with components down to 0.05% being detectable. However, measurements have been made on samples as little as 50 μg. The phosphorus nucleus needs a certain amount of time (the relaxation time) to return to the ground state after a pulse. This time depends on the chemical environment of the P atom. A total of 18 individual phospholipids have been identified and quantified including many minor and unusual phospholipid classes. Additional information about FAs, oxidation state, and byproducts can be derived from ^{1}H- and ^{13}C-NMR spectroscopy.

4.2 Chemical Classes

4.2.1 Glycerophospholipids and Sphingomyelins

Plasma very low density lipoprotein (VLDL), low density lipoprotein (LDL), high density lipoprotein (HDL) and chylomicrons possess distinct PtdCho, PtdEtn and SM compositions. These compositions differ from those of the red cell and platelet membranes and from the plasma membranes of the cells lining the vascular bed and atheroma. They also differ from those of the liver cell, where they are synthesized and assembled into the lipoprotein particles.

4.2.1.1 Plasma Lipoproteins The common phospholipid classes of plasma lipoproteins are readily determined by normal-phase HPLC with on-line ESMS (LC/ESMS) without prior modification of the lipids by enzymatic or chemical means. Figure 6 shows the total positive and negative ion current profiles recorded for the LDL from normal subjects.[78] Specifically, the phospholipids were resolved with a Supelcosil (25 × 0.46 cm ID) column using a linear gradient of 100% solvent A (chloroform–methanol–30% ammonium hydroxide, 80 : 19.5 : 0.5, v/v/v) to 100% solvent B (chloroform–methanol–water–30% ammonium hydroxide, 60 : 34 : 5.5 : 0.5, v/v/v/v) in 35 min.[22] The Cho-containing phospholipids (PtdCho, SM and lysoPtdCho, and PAF) are analyzed in the positive ion mode while the acidic phospholipids (PtdSer, PtdIns, PtdOH, PtdGro and cardiolipin) are analyzed in the negative ion mode. PtdEtn can be detected in both positive and negative ion modes, but the response is higher in the negative ion mode. This column resolves the Cho and sphingosine phospholipids into two or more peaks on the basis of chain length, with the longer chains being eluted earlier. However, determinations of minor components in the negative ion mode are compromised by the presence of significant amounts of chloride adducts of Cho-containing phospholipids. The phospholipid classes are identified from the specific head group ions and the molecular species from the diradylglycerol fragment ions obtained by MS/MS or pseudo MS/MS (LC/ES/CID/MS), where CID is obtained in a single quadrupole instrument by rerunning the sample at a higher capillary exit voltage. Plasmalogens elute later than the acyl phospholipids of corresponding chain length and degree of unsaturation. The method has been applied to phospholipid analyses in normal and acute phase human plasma HDL before and after hydrolysis with secretory phospholipase A_2.[79] The phospholipid classes are

Figure 6 Total negative (a) and positive (b) ion current profiles of total lipid extracts of human LDL by normal-phase LC/ESMS.[78] PtdEtn includes its alkyl and alkenyl ether; PtdCho includes its alkyl ether homologs; LysoPtdCho, lysophosphatidyl-choline including alkyl ether homologs. Column, Spherisorb 3 μ (100 mm × 4.6 mm ID, Alltech Associates, Deerfield, IL); solvent, linear gradient of 100% solvent A to 100% solvent B in 14 min, then solvent B for 10 min; solvent A, chloroform–methanol–30% ammonium hydroxide (80 : 19.5 : 0.5, v/v/v); solvent B, chloroform–methanol–water–30% ammonium hydroxide (60 : 34 : 5.5 : 0.5, v/v/v/v); Model 1060 liquid chromatograph interfaced with Hewlett-Packard Model 5988B quadrupole mass spectrometer equipped with a nebulizer-assisted electrospray interface. Ion spectra were taken in the mass range 300–1100.

readily quantified by including appropriate species of standard phospholipids with the LC/ESMS run (see section 4.3).

The glycerophospholipid and SM classes of plasma lipoproteins are readily resolved by TLC using chloroform–methanol–acetic acid–water (75 : 45 : 12 : 6, v/v/v/v) as solvent.[59,60] This solvent system yields essentially pure fractions of PtdCho, PtdEtn and SM, which are recovered from the silica gel by repeated extraction with chloroform–methanol–acetic acid–water (50 : 39 : 1 : 10, v/v/v/v).[80] To each eluate is added 4 mL of 1 M NH_4OH. The recovered PtdSer and PtdIns, which overlap, are resolved using chloroform–methanol–3 M ammonia (65 : 35 : 6.5, v/v/v) as solvent.[81] The relative proportions of these lipid classes are determined by analysis of phosphorus, FAs or of the dephosphorylated residues of the phospholipids, all of which have given similar results. Thus, while the diacyl GroPCho and SM comprise the bulk, the diradyl GroPEtn and PtdIns constitute minor components of plasma lipoproteins.

The glycerophospholipid fractions may also be resolved by TLC on commercially prepared silica gel G plates (20 × 20 cm, 250 μm thick layer) supplied by Analtech (Fisher Scientific, Boston, MA). PtdCho (retention factor, R_f 0.13) and PtdEtn (R_f 0.59) are isolated using chloroform–methanol–water (25 : 10 : 1, v/v/v, plus BHT) as the solvent.[80] PtdIns (R_f 0.32) is purified similarly using chloroform–methanol–acetic acid–water (50 : 30 : 8 : 4, v/v/v/v, plus BHT).[81] BHT is added as an antioxidant at 50–100 mg L^{-1} of solvent. The phospholipids are located by spraying with 0.1% 2,7-dichlorofluorescein in 95% methanol and by comparing the R_f values to those of reference standards. The phospholipids are recovered from the silica gel scrapings by extraction with chloroform–methanol (1 : 1, v/v) immediately after separation and before the plate has dried.

The phospholipid class composition of whole plasma is of the order reported previously on the basis of TLC separation and phosphorus analyses[82] or GLC analyses of the component FAs,[59] with 67% diradyl GroPCho, 17.7% SM, 2.5% diradyl GroPEtn and 2.1% diradyl GroPIns. The phospholipid composition of individual plasma lipoproteins has been reported by several groups of investigators using a variety of methods. The early data compiled by Skipski[83] remains to date the most complete reference to the phospholipid composition of VLDL, LDL and HDL phospholipids in man (Table 1). Detailed analyses of selected lipid classes of specific lipoproteins have been reported more recently, e.g. chylomicrons,[4] VLDL and LDL[53] and HDL_{2+3}.[84]

Breckenridge and Palmer[54] have reported the PtdIns and PtdIns P content of plasma VLDL, LDL and HDL in comparison to that of platelets and erythrocytes. HDL contained a greater proportion of PtdIns (2.6% of total phospholipid) than did either LDL or VLDL (1.6 and 1.7%, respectively). Breckenridge and Palmer[54] also quantitated the PtdSer of HDL, LDL and VLDL of human plasma.

Kuksis et al.[61] have used GLC to measure the content of the lysoPtdCho, PtdCho and SM of plasma lipoproteins as the monoacylglycerols, diacylglycerols and ceramides, respectively, released from the lipoprotein samples by phospholipase C, following trimethylsilylation and addition of an internal standard. The values derived for total plasma PtdCho (177 mg%) and SM (46 mg%) compared favorably to those obtained by TLC separation of the phospholipid classes and determination of phosphate (PtdCho, 165 mg% and SM, 47 mg%).

Table 1 Phospholipid composition of plasma and plasma lipoproteins as determined by different analytical methods (mol% of total phospholipids)

Components[a]	Plasma[82]	CHYLOS[5]	VLDL[83]	LDL[83]	HDL_{2+3}[83]

4.2.1.2 Red Cells and Platelets The major phospholipid classes of red cells and platelets are also readily detected and quantified by normal-phase LC/ESMS or by ESMS/MS as the intact molecules. Han and Gross[72] have reported direct analysis of phospholipid classes and molecular species of phospholipids by flow injection ESMS/MS. The various phospholipid classes are recognized and quantified by the yields of the individual molecular species measured in the presence of appropriate internal standards (e.g. 16 : 0–18 : 1 GroPSer, 14 : 0–14 : 0 GroPIns; 15 : 0–15 : 0 GroPCho; 15 : 0–15 : 0 GroPEtn).

Ravandi et al.[78] have employed LC/ESMS for the analysis of the red cell phospholipids of diabetic subjects. The Cho-containing phospholipids were detected and quantified in the positive ion current, while the Etn-containing phospholipids and the acidic phospholipids were determined in the negative ion mode. Two or three peaks each due to a partial fractionation by chain length on the adsorbent column were found. Summation of the peak areas and correction for differences in ion yields provides valid estimates of the phospholipid class content of the red cells. In the LC/ESMS method the lipid classes are quantified on basis of the parent ion intensities.

Individual phospholipid classes of the red cells can be resolved by unidimensional TLC of the total lipid extract using chloroform–methanol–acetic acid–water (75 : 45 : 12 : 6, v/v/v/v) as solvent,[60] and are recovered from the silica gel by repeated extraction with chloroform–methanol–acetic acid–water (50 : 39 : 1 : 10, v/v/v/v) as described for plasma lipoproteins. The relative proportions of the various lipid classes estimated on the basis of the derived diacylglycerol and ceramide moieties or of FA analyses in the presence of internal standards found by this method are similar to those recorded by earlier workers who estimated the phosphorus content of the resolved lipid classes.[83]

Mallinger et al.[85] have described a two-dimensional TLC method, based on several novel modifications of existing techniques, for concurrently analyzing nanomolar amounts of nine phospholipid classes in a single aliquot of red cell membrane extract. The phospholipid classes are first separated by two-dimensional TLC and then determined using two-dimensional scanning laser densitometry. Tables 2 and 3 give relative phospholipid composition of erythrocyte and platelet membranes from control subjects using acidic extraction of washed membranes. The data obtained by densitometric measurements compare closely to those obtained in an earlier

Table 2 Relative phospholipid composition of erythrocyte membranes from control subjects (mol%)

study by Mitchell et al.,[86] in which radiolabeling with ^{32}P and quantification by phosphate assay were used.

Studies using membrane impermeant reagent TNBS have shown that aminophospholipids are primarily localized on the plasma membrane interior of the red cell, although some of the PtdEtn is found on the cell surface.[70] Han et al.[76] have used ESMS/MS to measure the alterations in individual phospholipid classes and molecular species of platelet phospholipids during thrombin stimulation. By exploiting the analytical power and sensitivity of ESMS they have identified plasmenylethanolamines as the largest source of arachidonic acid mass during thrombin stimulation.

Figure 7 shows a TLC separation of human platelet phospholipids as obtained with chloroform–methanol–acetic acid–water (50 : 37.5 : 3.5 : 2, v/v/v/v) as the developing solvents.[87] This system has been routinely employed to separate PtdIns from PtdSer on precoated commercial silica gel H plates (E. Merck).

Figure 7 Separation of PtdIns and major cellular phospholipids by one-dimensional TLC.[87] NL, neutral lipid; other lipid classes as described in text. Adsorbent: precoated silica gel H plates (E. Merck). Solvent system: chloroform–methanol–acetic acid–water (50 : 37.5 : 3.5 : 2, v/v/v/v).

4.2.1.3 Atheroma Although the chemical composition of neutral lipids contained in the atherosclerotic plaque has been extensively investigated, relatively few studies have focused on the phospholipid content.[88] The most extensive study has been performed by Katz et al.[42] The techniques utilized for the determinations of the phospholipids were TLC with densitometry which indicated that atherosclerotic plaques contain close to 20% phospholipids. The value is dependent on the age of the plaque and the severity of the lesion. Table 4 shows that the major phospholipid classes present in the atherosclerotic plaque are PtdCho, SM and lysoPtdCho. PtdEtn and PtdIns are also in most atherosclerotic lesions and amount to 2–3% of the total lipid weight.

4.2.2 Phosphatidylinositol Phosphates

The PtdIns phosphates have been selected for special attention here because the usual chromatographic and mass spectrometric methods do not resolve or detect them because of the high polarity of these compounds and their low abundance in blood plasma and cells. This results in a partial repetition of the coverage in previous sections because some of the methods which detect the PtdIns phosphates also detect the other phospholipids.

4.2.2.1 Red Cells Although standard PtdIns phosphates from polymorphonuclear leukocytes (neutrophils from heparinized human blood) have been analyzed by matrix-assisted laser desorption/ionization (MALDI) MS,[89] there appear to have been no such attempts to analyze the phosphoinositides of red cells or platelets. The MALDI mass spectra of polyphosphoinositides with different degrees of phosphorylation were complicated by charge compensation. The content of polyphosphoinositides in stimulated neutrophils was judged too low for recognition of the anticipated ions.

Therefore, the analyses of phosphoinositide phosphates of red cells must rely on TLC and HPLC analyses. TLC on silica gel HL (Analtech, Inc., Newark, DE; not

Table 4 Phospholipid composition for newborn intima and each class of atherosclerotic lesion (wt% of total lipid)[42]

activated) with methanol–chloroform–water–concentrated ammonia (48:40:10:5, v/v/v/v) separated the inositides from origin and resolved the three radioactive lipids obtained by incubating the red cells with ^{32}P for 18–30 h.[90] Typical R_f values were PtdIns (4,5)P_2, 0.38; PtdIns (4)P, 0.46; lysoPtdCho, 0.56; PtdOH, 0.60; SM, PtdSer, PtdIns, and lysoPtdEtn, 0.60–0.66; PtdCho, 0.72, PtdEtn, 0.79; and cholesterol, 0.98.

A rapid two-dimensional TLC system which resolves the four phosphoinositide cycle phospholipids as well as all commonly encountered major and minor phospholipids has been described by Mitchell et al.[86] The samples are applied to TLC plates (10 cm × 10 cm), cut from Polygram 20 × 20 cm SIL H-HR plastic backed plates (Camb) and the plates developed first in chloroform–methanol–water–concentrated ammonia (48:40:7:5, v/v/v/v), and then at 90 °C in chloroform–methanol–formic acid (55:25:5, v/v/v). Recoveries are of the order of 85%.

Mallinger et al.[85] have utilized HPTLC plates for two-dimensional separation of red cell and platelet phospholipids including the PtdIns phosphates. Prior to being developed the plates were activated by heating to 100 °C for 15 min. Samples of lipid extract (approximately 2.5 μL) containing 1.8–2.0 μg of phosphorus were applied to HPTLC plates with a 10 μL Hamilton syringe. The plates were developed at room temperature. The first dimension was performed with chloroform–methanol–4.3 M NH_4OH (90:65:20, v/v/v) to resolve the polyphosphoinositides. The plates were then dried and developed a second time in the first dimension with chloroform–methanol–concentrated NH_4OH (130:50:10, v/v/v) in order to separate lysoPtdEtn from PtdCho. Then the plates were rotated 90° and developed in the second dimension with chloroform–methanol–acetic acid–water (100:30:35:3, v/v/v/v) to resolve the remaining phospholipid classes. The plates were then dried thoroughly and visualized and quantified by charring. PtdIns is the major inositol phospholipid in red cells, but appreciable quantities of the PtdIns (4)P and PtdIns (4,5)P_2 are also found (Table 2).

PtdIns P (PtdIns (3)P and PtdIns (4)P), PtdIns P_2 (PtdIns (3,4)P_2 and PtdIns (4,5)P_2) and PtdIns P_3 can clearly be separated by TLC, as noted above; the resolution of the D-3/D-4 isomers of PtdIns P and PtdIns P_2 is critical. A few protocols on this subject have been published. Some of them provide separation of PtdIns (3)P from PtdIns (4)P and others of PtdIns (3,4)P_2 from PtdIns (4,5)P_2. Hegewald[91] has described the first protocol for the separation of D-3 and D-4 PtdIns P lipids. The chromatography is performed on two different types of HPTLC plates under otherwise identical conditions and depends on the ability of the D-4, but not D-3, isomers to form complexes with boric acid. For this purpose precoated HPTLC plates of silica gel 60F254, Art 1.056641, and HPTLC plates NH_2, Art 1.12572, are used (both from Merck). Reference standards, ^{32}P-labeled PtdIns (4)P, PtdIns (4,5)P_2 and PtdOH were produced by in vitro incubation of human erythrocyte membranes with Mg-[γ-^{32}P]ATP and the lipids were extracted with hexane–2-propanol–HCl mixtures, essentially as described by Myher et al.[60] ^{32}P-Labeled PtdIns (3)P, PtdIns (3,4)P_2, and PtdIns (3,4,5)P_3 are synthesized by the incubation of a sonicated mixture of the erythrocyte lipids with Mg-[γ-^{32}P]ATP and the recombinant PtdIns-3-kinase γ. Hegewald et al.[92] impregnated the HPTLC plates by dipping them upside down into 5% boric aid (w/v) solution in methanol and then drying them for 5 min in an air current. Samples containing about 0.01 to 0.1 mg lipid are applied (CAMAG-Linomat IV, Switzerland) as 10 mm lanes, 10 mm above the bottom edge of the plate. The plates, which needed not to be activated, are then developed in 1-propyl acetate–2-propanol–absolute ethanol–6% aqueous ammonia (3:9:3:9, v/v/v/v), in a well equilibrated paper-lined twin-trough chamber (CAMAG). The mobile phase is allowed to reach the top of the plates (about 2 h). Following chromatography, the dried plates are dipped in charring reagent (5% $CuSO_4$ solution in 8% aqueous H_3PO_4) and heated at 180 °C for 15 min. The radioactivity of the ^{32}P-containing phospholipids is visualized and quantified using the GS-250 Molecular Imager System (Bio-Rad Laboratories, Hercules, CA).

4.2.2.2 Platelets The polyphosphoinositides (PtdIns P and PtdIns P_2) of platelets have been resolved by one-dimensional TLC using chloroform–methanol–ammonium hydroxide–water (45:35:6:4, v/v/v/v) as an effective developing solvent in combination with home-made silica gel H plates.[87] In this solvent system, PtdIns P, PtdIns P_2, lysoPtdIns and PtdOH are well resolved, but the separation of PtdIns from other phospholipids is poor. However, one-dimensional TLC separation can be readily used for the inositide separation if the study includes the use of [^{3}H]inositol-labeled lipids from platelets. The basic system containing chloroform–methanol–4M ammonium hydroxide (45:35:10, v/v/v) has been used to separate PtdIns, PtdIns P, and PtdIns P_2 from stimulated human platelets using oxalated silica gel H plates.[87] Using a chloroform–methanol–ammonium hydroxide–water (45:35:8:3, v/v/v/v) system, the following R_f values are obtained: PtdIns, 0.39; lysoPtdIns, 0.32; PtdIns P, 0.19; lysoPtdIns P, 0.07; and PtdIns P_2, 0.02. An increase in the water content from three to four parts in the solvent system will moderately raise the R_f values for PtdIns P and PtdIns P_2.

Mitchell et al.[86] used two-dimensional development on conventional TLC plates to separate the phospholipid

classes of platelets including the polyphosphoinositides as described above for the red cells, while Mallinger et al.[85] employed two-dimensional HPTLC for the resolution of the polyphosphoinositides of human platelets as described above for the red cells. Table 3 compares the relative composition of platelet membrane phospholipids obtained by the methods of Mitchell et al.[86] and Mallinger et al.[85] Excellent separations were obtained in both instances, although the isomeric PtdIns Ps were not resolved. Binder et al.[93] have described an HPLC method for the separation of polyphosphoinositides. A Bondapak NH_2 column (30×0.30 cm) is employed. Separation is carried out utilizing a 20 min isocratic elution with a 60 or 75 mM ammonium acetate–acetic acid buffer, pH 4.0, followed by a 120 min linear gradient to 2 M ammonium acetate–acetic acid, pH 4.0, at a flow rate of 1 mL min^{-1}. The PtdIns is the first one to be eluted from the column (15–20 min) followed by PtdIns P (40–55 min) and PtdIns P_2 (65–80 min). This procedure has been validated by monitoring changes in the phosphoinositides of human platelets stimulated with thrombin.

4.3 Molecular Species

The glycerophospholipids of plasma and cells contain nonidentical and nonrandom associations of fatty chains, attached by ester or ether linkages, with chain lengths of 16–22 carbons and up to six double bonds, whereas SM is made up of a separate pool of FAs and nitrogenous bases joined by amide linkages. This results in several hundreds of chemically distinct species of phospholipids.

In the past, the resolution of molecular species was obtained following an initial separation of the lipid classes, which are then examined separately after a chemical or enzymatic transformation, if necessary. This approach is still the best and can be effectively combined with HPLC and on-line ESMS. However, direct (flow) injection ESMS/MS of total phospholipid mixture saves time and frequently yields comparable results.

4.3.1 Glycerophospholipids

Until recently, when soft ionization MS became available, molecular species of blood glycerophospholipids, with few exceptions, were resolved and quantified by high-temperature GLC[20,58,59,60,94,95] or HPLC[16,62,70,71,87,93–97] following removal of polar head groups and trimethylsilylation or preparation of UV-absorbing derivatives, respectively. Soft ionization MS/MS now permits analysis of molecular species of most phospholipid classes without prior derivatization.

4.3.1.1 Plasma Lipoproteins A normal phase LC/ESMS of a total lipid extract yields separate peaks for different phospholipid classes, which can be examined by means of single ion mass chromatograms extracted from the total ion profile or by single ion monitoring, which is more sensitive. LC/ESMS currently provides the most effective method of determining the molecular species of glycerophospholipids.[21,98,99] Ravandi et al.[99] have used LC/ESMS for the determination of the molecular species of Etn glycerophospholipids of LDL. Table 5 tabulates the molecular species of the diradyl GroPEtn from human LDL. The molecular species were calculated from the total ion current profiles shown in Figure 6. Further accuracy in the LC/ESMS assay of molecular species of glycerophospholipids is obtained by substituting a reversed-phase for the normal-phase HPLC column. Pruzanski et al.[79,84] have used the normal-phase LC/ESMS method to identify and quantify the molecular species of phospholipids of normal and acute phase HDL. The Cho-containing glycerophospholipids were determined in the positive ion mode, while the Etn-containing and acidic phospholipids were determined in

Figure 8 Single ion chromatograms of molecular species of residual PtdChos of acute phase HDL (APHDL) hydrolyzed with secretory group IIA phospholipase A_2 at 0 h (a) and 4 h (b) of hydrolysis.[79] Peak identification is given. LC/ESMS conditions are as given in Figure 6. Single ion chromatograms were retrieved from the total ion spectra by computer. FA abbreviations are as described in the text. Alkenyl designates the vinyl ether species of PtdCho. (Reproduced with permission from Pruzanski et al.[79])

the negative ion mode. Figure 8 shows the single ion mass chromatograms of molecular species of residual PtdCho of acute phase HDL hydrolyzed with secretory group IIA phospholipase A_2 at 0 (Figure 8a) and 4 (Figure 8b) h of hydrolysis. For quantification of the different molecular species an internal standard is included and the response is calibrated for each phospholipid class. Table 6 compares the molecular species of the PtdCho of normal human HDL and acute phase HDL. Only minor differences in the molecular species were noted despite marked differences in the composition of the associated proteins.[84]

Prior to chromatographic and mass spectrometric resolution of intact phospholipids, the molecular species of glycerophospholipids and SMs had been determined by high-temperature GLC of the TMS and TBDMS ethers of the diacylglycerol moieties released by phospholipase C.[59,60] The purified TBDMS ethers are resolved by carbon number using a nonpolar column (8 m × 0.32 mm ID fused silica capillary) coated with a cross-linked 5% phenylmethylsilicone (Hewlett-Packard). The sample is injected on-column and the temperature is programmed in four steps from 40 to 350 °C: 40 to 150 °C at 30 °C min^{-1}; then to 230 °C at 20 °C min^{-1}; then to 280 °C at 10 °C min^{-1}; and to 340 °C at 5 °C min^{-1}. The carrier gas is H_2 at 6 psi (1 psi = 6.9 kPa) head pressure. The purified TBDMS ethers are resolved into molecular species by GLC on a polar column (15 m × 0.32 mm capillary coated) with SP2380 (Supelco, Oakville, Ontario, Canada), which is operated isothermally (260 °C) or is temperature programmed from 240 to 260 °C at 5 °C min^{-1} with hydrogen as carrier gas at 2 psi head pressure. These analyses have provided the most extensive compilation of the analytical data for total

[b] APHDL isolated from eight pools of acute phase plasma from patients in various states of fasting.

plasma lipoproteins.[60] Qualitatively the data for total plasma are identical to the data for individual plasma lipoproteins, but quantitatively significant differences are noted. Figure 9 shows the elution patterns obtained on polar capillary GLC for the TMS ethers of the alkylacylglycerols derived from plasma alkylacyl GroPCho (Figure 9a) and alkylacyl GroPEtn (Figure 9b) respectively. Although both Cho and Etn GPL contain nearly identical proportions of 16:0′–20:4 and 18:0′–20:4 species, the alkylacyl GroPCho contain much more of the saturated, monoenoic and 18:1′–20:4 and 16:0′–22:4, and less of other polyunsaturated species than alkylacyl GroPEtn. Yang et al.[5] have used polar capillary GLC for the resolution of the molecular species of chylomicron PtdCho as the diacylglycerol TMS ethers from corn and fish oil feeding. Breckenridge and Palmer[54] compared the FA composition of the PtdIns among human plasma lipoprotein classes as an indication of the composition of molecular species. It is found that the PtdIns from VLDL, LDL and HDL gave the same FA composition,

Figure 9 Polar capillary GLC profile of the alkylacylglycerol moieties of human plasma diradyl (a) GroPCho and (b) GroPEtn.[60] Peak identification is given. Sample: 1 mL of 0.1% diradylglycerol TMS ethers in hexane. GLC conditions: column, 15 m × 0.32 mm fused silica capillary coated with cross-bonded RTx 2330; carrier gas, H_2, 3 psi; temperature, 250 °C, isothermal. (Reproduced with permission from Myher et al.[60])

but had less 20:4n6 than platelet PtdIns and less 16:0 than erythrocyte PtdIns.

Myher et al.[4,59] have reported the molecular species of the SMs of plasma lipoproteins. The species were determined by GLC following dephosphorylation by phospholipase C and trimethylsilylation.

4.3.1.2 Red Cells and Platelets Han and Gross[72] have reported direct analysis of the molecular species of erythrocyte phospholipids by flow injection ESMS/MS. Quantitative analysis of individual molecular species from subpicomole amounts of human erythrocyte phospholipids are reported with a sensitivity two to three orders of magnitude greater than that achievable with fast atom bombardment mass spectrometry (FAB/MS). More than 50 phospholipid constituents were identified in human erythrocyte plasma membrane by direct ESMS of chloroform extracts derived from the equivalent of <1 μL of whole blood (Figure 10). Isobaric molecular species of both PtdCho and PtdEtn are identified and quantified by ESMS/MS. The analysis included estimates of the three major Cho phosphatide subclasses: plasmenylcholine, plasmanylcholine and PtdCho. Kerwin et al.,[55] however, observed that ESMS is not capable of differentiating in all instances between alkylacyl and alkenylacyl substituents without prior separation of these lipid subclasses.

Figure 10 Direct ESMS analysis of human erythrocyte plasma membrane phospholipids.[72] (a) A positive-ion electrospary ionization mass spectrum of erythrocyte plasma membrane phospholipid extract (containing 13.5 pmol of Cho glycerophospholipids from 25 nL of whole blood) shows 14 molecular species of Cho glycerophospholipids, e.g. *m/z* 757, 781, 783, 805, 809, and 833, corresponding to sodiated 16:0–16:0, 16:0–18:2, 16:0–18:1, 16:0–20:4, 18:0–18:2 (18:1–18:1) and 18:0–20:4 GroPCho, respectively, as well as *m/z* 767, 795 and 823, corresponding to sodiated 16:0–18:1, 18:0–18:1 and 18:0–20:1 plasmenyl Cho, respectively, and four molecular species of SM, e.g. *m/z* 726, 754 and 782, corresponding to 16:0, 18:0 and 20:0 amides. (b) A negative-ion electrospary ionization mass spectrum of the same extract of plasma membrane phospholipids shows >25 molecular species of Etn glycerophospholipids, predominantly composed of plasmalogen molecular species, e.g. *m/z* 751, 723, 749, 775, 777, and 779, corresponding to 18:0–20:4, 16:0–20:4, 18:1–20:4, 18:0–22:6 (18:1–22:5), 18:0–22:5 (18:1–22:4) and 18:0–22:4 (20:0–20:4) plasmenyl Etn, respectively. In addition, PtdEtn species were detected at *m/z* 715, 717, 739, 765, 767 and 793, corresponding to 16:0–18:2, 16:0–18:1, 16:0–20:4, 18:1–20:4, 18:0–20:4 (16:0–22:4) and 18:0–22:5 (18:1–22:4), respectively. Molecular species of other acidic phospholipids were seen at *m/z* 811, 833 and 886, corresponding to 18:0–20:4 GroPSer, 18:1–22:6 GroPSer, and 18:0–20:4 GroPIns, respectively. (c) ESMS/MS analysis of isobaric Etn glycerophospholipids (*m/z* 777) extracted from human erythrocyte plasma membranes with selection and CID of *m/z* 777 after negative-ion electrospray ionization demonstrates two carboxylic anions (*m/z* 329 and 331) (see Inset), corresponding to 22:5 and 22:4 FAs, respectively. The sample, in 30 μL of chloroform–methanol (1:2, v/v) in the presence of excess NaOH (i.e. NaOH/lipid molar ratio > 1), was infused directly into the electrospray chamber with a syringe pump at a flow rate of 1.5 μL min^{-1} for mass analyses in both negative- and positive-ion modes. (Reproduced with permission from Han and Gross.[72])

Furthermore, ESMS did not provide information on the position (*sn*-1 or *sn*-2) of FAs, although such differentiation has occasionally been observed.[56]

Furthermore, the major molecular species of the diacyl GroPCho compare favorably to those reported in earlier GLC analyses,[94,100] while those of the diradyl GroPEtn are not unlike those assessed by Hullin et al.[70]

Hullin et al.[16] have obtained distinct HPLC profiles for the trinitrophenyl derivatives of human red blood cell GroPEtn before and after acidolysis, which destroys the plasmalogens. Using this method, Hullin et al.[16] are able to separate and quantify the molecular species of both subclasses (diacyl and alkenylacyl) from human red blood cells and rat brains with a lower limit of detection of about 10 pmol. The method provides a useful addition to the repertoire of analytical procedures for the determination of the molecular species, as well as for the study of molecular species asymmetry in biological membranes. PtdEtn and PtdSer, after N-derivatization to improve their chromatographic properties, have been subjected to mass spectrometric examination with thermospray following reversed-phase HPLC.[16] This compares to over 200 species determined by capillary GLC of the diradylglycerol TMS ethers following dephosphorylation.[59]

The most exhaustive analyses of the molecular species of the glycerophospholipids of red cells have been performed by polar capillary GLC on the alklyacyl, alkenylacyl and diacylglycerol moieties as the corresponding TMS ethers.[59] Figure 11 shows the polar capillary GLC profiles of PtdIns and PtdSer of the red

Figure 11 Polar capillary GLC profile of the diacylglycerol moieties of human red blood cell diacyl (a) GroPIns and (b) GroPSer. Peak identification is given. Conditions as in Figure 9. (Reproduced with permission from Myher et al.[59])

blood cells, which contain only the diacylglycerol subclass. The quantitative composition of the molecular species of red cell diacyl glycerophospholipids is given in Table 7 along with that of the diacyl GroPCho and GroPEtn. There are marked differences between the major and minor molecular species among the different glycerophospholipid classes. Thus, while the diacyl GroPCho and diradyl GroPEtn contain closely similar amounts of 16:0–18:1n9 (18.0 vs 15.1%), 18:0–18:1n9 (5.8 vs 4.3%) and 16:0–20:3n6 (5.2 vs 3.5%), they differ greatly in the content of 16:0–18:2n6 (26.9 vs 6.2%), 18:0–18:2n6 (11.2 vs 2.1%), 16:0–20:4n6 (5.1 vs 13.5%), 18:0–20:4n6 (3.9 vs 12.6%) and 18:1n9–20:4n6 (0.6 vs 8.4%). In contrast, the diacyl GroPIns and GroPSer contained closely similar amounts of 18:0–20:4n6 (18:0–20:3n6) (45.3 vs 47.4%), 18:0–18:1n9 (3.6 vs 5.9%) and 18:1–20:3 + 18:1t–20:4 (4.5 vs 4.9%), but differed in the content of 18:0–22:4n6 (2.3 vs 11.3) and 18:0–22:5 plus 18:0–22:6n3 (2.8 vs 21.0).

Detailed GLC analysis has also been performed on alkylacylglycerols derived from the erythrocyte diradyl GroPCho and GroPEtn showing marked differences in both qualitative and quantitative composition, which indicates that the alkylacylglycerols represent different pools of molecular species. While the alkylacyl GroPCho and GroPEtn contain nearly identical proportions of 16:0′–20:4 and 18:1′–20:4 species, the alkylacyl GroPCho contains much more of the saturated and monoenoic and less of the 18:0′–20:4, 16:0′–22:4, 18:0′–22:4 and other polyunsaturated species than alkylacyl GroPEtn.

There are significant differences between the two lipids in the composition of the alkenylacyl species indicating the existence of separate pools of precursors or independent transformation mechanisms. The alkenylacyl GroPCho is much richer in species in which a 16:0″ alkenylglycerol is combined with saturated, monoenoic, dienoic and tetraenoic FAs, whereas alkenylacyl GroPEtn is much richer in 18:0″ alkenylglycerol combined with dienoic, tetraenoic and hexaenoic FAs. The positional distribution of the fatty chains in the individual diacyl GroPCho and GroPEtn is not independently determined: thus, the relative proportions of the reverse isomers have not been estimated. The phospholipase A_2 data are available in the literature[101] and we have taken advantage of them in compiling the tabulated material.

In contrast to red cells, Schick et al.[102] found that the molecular species of the Etn phospholipids of human platelet plasma membrane cell surface did not differ from those of the inside, except in regard to 18:2n6.

Han et al.[76] have applied the flow injection ESMS method to the determination of individual molecular species of human platelet phospholipids. Figure 12 compares the negative-ion electrospray ionization mass spectra of PtdEtn and related lipids in resting and thrombin-stimulated human platelets. The control platelet phospholipids demonstrated that alkenylacyl glycerophosphoethanolamine (PlsEtn) is the predominant Etn glycerophospholipid subclass in human platelets [peaks at *m*/*z* 723 (16:0–20:4 and 18:2–18:2 PlsEtn), 749 (18:1–20:4 and 16:0–22:5 PlsEtn), 751 (18:0–20:4 and 16:0–22:4 PlsEtn), and 779 (18:0–22:4 and 20:0–20:4 PlsEtn)]. The thrombin-stimulation resulted in a 53% decrease in mass during 90 s resulting in the liberation of 20.1 nmol of arachidonic acid/10^9 platelets from the PlsEtn pool (Table 8). Thus, the most abundant PlsEtn species 18:0–20:4 underwent a 57% decrease in mass. The quantitative accuracy of human platelet anionic phospholipid determinations is substantiated by

Figure 12 Negative ion electrospray ionization mass spectra of Etn glycerophospholipids in resting and thrombin-stimulated human platelets.[76] (a) A negative-ion electrospray ionization mass spectrum of membrane extract from resting human platelets was obtained in the presence of NaOH in chloroform–methanol (1 : 2, v/v). Individual Etn glycerophospholipid molecular species were identified utilizing ESMS/MS and are listed in Table 8. The internal standard is 18 : 3–18 : 3 PtdEtn. (b) A negative-ion electrospray ionization mass spectrum of membrane extract from thrombin-stimulated human platelets was acquired under identical conditions. The insert is an expanded mass spectrum of the region around *m*/*z* 735 obtained from platelet extracts which did not contain exogenously added 18 : 3–18 : 3 PtdEtn which demonstrates that no endogenous molecular ions are present in this region. (Reproduced with permission from Han et al.[76])

co-addition of known amounts of either 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoserine or bovine liver PtdIns with dimyristoylGroPSer as internal standard in chloroform–methanol (1 : 1, v/v) to the platelet suspension prior to Bligh and Dyer extraction and ESMS analyses.[76] A comparison of the MS/MS estimates to the estimates obtained by HPLC revealed great discrepancies apparently due to incomplete resolution of molecular species under the selected HPLC conditions, which led to inappropriate summing of the molecular species for comparison to MS/MS data. The alkenylacyl molecular species may be distinguished from alkylacyl GroPEtn molecular species by treating human platelet phospholipid extracts with acidic vapors prior to mass spectroscopic analyses as described previously.[71,72]

Kim and Salem, Jr[47] have reviewed the early applications of LC/MS of lipids, including references to plasma lipoproteins and red blood cells. Thermospray spectra of plasmalogens contain prominent monoacylglyceryl fragments resulting from a cleavage of the alkenyl moiety at the *sn*-1 position from the diradylglycerol fragments. The alkylacyl GroPCho, like PtdCho, yields diacylglycerol-like fragments as the base peaks. While a PAF molecule produced diacylglyceryl fragments, head group and molecular ions, 1-acyl analogs also produced monoacylgyceryl fragments including a peak at *m*/*z* 117 which arose from the hydrolysis of the 1-acyl moiety from the diacylglyceryl fragment.

Earlier effective chromatographic resolution of molecular species of intact glycerophospholipids was reported by Patton et al.[96] using reversed-phase HPLC. Patton et al.[97] applied this method to the separation of the molecular species of the glycerophospholipids of rat plasma HDL, and rat lymph HDL and VLDL. Since the various diradylglycerol species are not separated, the diacyl, alkylacyl and alkenylacyl GroPCho and GroPEtn subclasses must be first resolved by some other means (see above). A comparison between the total and the diacylglycerol subclasses is possible, however, as the latter may be recovered along with the alkylacylglycerol species following treatment with acid vapor.[71,72] The molecular species are detected by short-wave UV (205 nm).

4.3.2 Sphingomyelins

Like the molecular species of the glycerophospholipids, those of the SMs in the past were determined by GLC following removal of the polar head group and

silylation.[4,20,59,60] Soft ionization MS now permits analysis of molecular species of most phospholipid classes without prior derivatization.

4.3.2.1 Plasma Lipoproteins The first detailed analyses of the molecular species of SMs of human plasma lipoproteins were made by Myher et al.,[4] who used high-temperature GLC and trimethylsilylation to resolve the ceramide moieties released by phospholipase C. The molecular species of the di-TBDMS ethers of ceramides were determined by gas chromatography/mass spectrometry (GC/MS)[4] using nonpolar columns. The molecular species are first resolved by carbon number by GLC and the species within each carbon number are determined by GC/MS. The composition by molecular weight was determined from the $[M - 57]^+$ ions. Much improved resolution of the molecular species of the ceramides released from the SMs by phospholipase C is obtained using polarizable capillary columns.[103]

Pruzanski et al.[79,84] have determined the molecular species of HDL SMs using normal-phase LC/ESMS. In one study[79] detailed analyses of the species was used to demonstrate resistance control and acute phase HDL SM to hydrolysis with secretory phospholipase A_2. In the other,[84] detailed comparisons were made between molecular species of control and acute phase HDL SMs. There was a close agreement between the present estimates obtained by LC/ESMS and the earlier GLC analyses of the ceramide moieties of SMs of control HDL.[4]

4.3.2.2 Red Cells and Platelets The first detailed analyses of the molecular species SMs of red cells were also made by nonpolar capillary GC/MS of the ceramide moieties. Much improved resolution and identification of

the ceramide moieties was obtained by polarizable capillary GC/MS of the TBDMS ether derivatives.[103] It must be noted, however, that human erythrocyte membranes have been found to contain free ceramides[104] (5.6 μmol/100 mL of packed cells). The free ceramide is constituted mainly of 16:0, 22:0, 24:0 and 24:1 nonhydroxy FAs and of 18:1 sphingosine.

Han and Gross[72] used flow ESMS and ESMS/MS for the determination of molecular species of human erythrocyte plasma membrane SM. The sensitivity of ESMS is two to three orders of magnitude greater than that achievable with FAB/MS. Multiple molecular species of SM are demonstrated, including species at *m/z* 726, 754, and 782, corresponding to the 16:0, 18:0 and 20:0 amides of sphingosine.

Kerwin et al.[55] have reported the positive and negative ion ESMS and ESMS/MS for commercial preparations of SM. The samples are analyzed by flow ESMS. Molecular ion adducts are the primary products formed by positive ionization, e.g. $[M + H]^+$, $[M + Na]^+$ and others. The negative spectra contained the ions corresponding to the loss of these groups. Positive ion MS/MS of $[M + H]^+$ ions yielded a strong peak at *m/z* 184 corresponding to the phosphocholine head group. In negative ion MS/MS spectra, the major ion found is the result of a loss of acetate from the parent ion described above. Less intense peaks are due to the loss of acetate and an additional CH_3 from the head group. Attempts to increase fragmentation to generate peaks characteristic of the N-acyl and sphingenine/sphinganine constituents using 1% methanolic formate are not successful.

An earlier method for the separation of molecular species of SM by reversed-phase HPLC has been described by Jungalwala et al.[105] SM species from bovine brain and sheep and pig erythrocytes are resolved into 10–12 separate peaks on a μBondapak C_{18} reversed-phase column with methanol–5 mM potassium phosphate buffer, pH 7.4, 9:1 (v/v) as the solvent. Detection is by UV at 203–205 nm. The molecular species are identified by peak collection and determination of the FA and nitrogenous base composition. Jungalwala et al.[105] combined HPLC with MS for improved identification and quantification of the molecular species of the resolved SM.

4.3.2.3 Atheroma The most extensive analysis of atherosclerotic phospholipids has been carried out by Ravandi et al.[98] Utilizing an LC/ESMS system many of the molecular species in each class of phospholipids were identified. In Table 9 over 22 species of Etn phospholipids were identified in which 64.89% consisted of alkenylacyl and 35.11% diacyl species. Although there are differences among species, there is an overall similarity in the composition of PtdCho and SM between LDL and atherosclerotic plaques. Other workers have reported the FA profiles of total lipid and total phospholipid fractions from atheroma.[26,28,42]

5 NOVEL PHOSPHOLIPID SUBCLASSES

The recent development of soft ionization mass spectrometric techniques has allowed the isolation and identification of various complex derivatives of the common glycerophospholipids. Analyses of these molecules had been difficult or impossible by conventional chromatographic and mass spectrometric methods because of instability and high polarity of the molecules. The modified compounds include the glycation products of the aminophospholipids, oxidation products of glycerophospholipids, and phosphoinositide glycans. The polyphosphoinositides, which would also belong to this group of compounds because of high polarity and instability, have been considered along with the common phospholipid classes because of their long-standing recognition.

5.1 Glycated Aminophospholipids

5.1.1 Plasma Lipoproteins

Nonenzymatic glycosylation is the post-translational modification of a protein by the covalent attachment of a sugar residue, which results in a spontaneous amino–carbonyl bonding referred to as a Schiff base linkage. Recently it has been shown that aminophospholipids are also susceptible to this reaction and glycated aminophospholipids can be isolated from in vivo sources.[78,99] The complex lipid mixtures require chromatography and MS for complete determination of the

Figure 13 LC/ESMS analysis of total lipid extract of LDL incubated with 50 mM glucose for 7 days.[98] (a) Total negative ion current profile of LDL phospholipids; (b) single ion plots for the major glucosylated PtdEtn and plasmenyl Etn species; (c) averaged spectra from the glycated PtdEtn peak (15.05 to 15.75 min). Peak identification is given. Cl, chloride adducts; diradyl, combined area of diacyl, alkylacyl and alkenylacyl moieties of PtdEtn. LDL total lipid extract was dissolved in chloroform–methanol (2 : 1 , v/v) and 20 µL of the sample containing 10 µg lipid was analyzed. LC/ESMS conditions: normal phase 5 µ Spherisorb column (250 mm × 4.6 mm ID) eluted with a linear gradient of 100% solvent A (chloroform–methanol–30% ammonium hydroxide, 80 : 19.5 : 0.5, v/v/v) to 100% solvent B (chloroform–methanol–water–30% ammonium hydroxide, 60 : 34 : 5.5 : 0.5, v/v/v/v) in 14 min, then at 100% solvent B for 10 min at 1 mL min^{-1}. The effluent was split by 1/50 resulting in 20 µL mL^{-1} being admitted into the mass spectrometer and scanning in the negative ion mode from 400 to 1100 amu. (Reproduced with permission from Ravandi et al.[98])

Figure 13 (*Continued*)

structure. As a reference standard Glc PtdEtn is prepared and purified as described previously.[22] Briefly, PtdEtn (2 mg) dissolved in 1 mL of methanol is transferred to a 15 mL test tube and the solvent evaporated under nitrogen. Then, 4 mL of 0.1 M phosphate buffer containing 0–400 mM glucose and 0.1 mM EDTA are added and sonicated at low power for 5 min at room temperature and the mixture incubated under nitrogen at 37 °C for various periods of time. Lipids are extracted into chloroform–methanol (2 : 1, v/v) as described by Folch et al.[18] and the solvents evaporated under nitrogen. Samples are redissolved in chloroform–methanol (2 : 1, v/v) and kept at −20 °C until analysis. Glc PtdEtn (2 mg) is purified by preparative TLC (20 × 20 cm glass plates) coated with silica gel H (250 μm thick layer). The chromatoplates are developed using chloroform–methanol–30% ammonia (65 : 35 : 7, v/v/v) as described.[22] Phospholipids are identified by co-chromatography with appropriate standards, visualizing any lipid bands under UV light after spraying the plate with 0.05% 2,7-dichlorofluorescein in methanol. Both glucosylated and nonglucosylated lipids are recovered by scraping the gel from appropriate areas of the plate and extracting it twice with the developing solvent.

Figure 13 shows the results of the LC/ESMS analysis of phospholipids from LDL preparations containing Glc-PtdEtn (Figure 13a). The Glc-PtdEtn is well resolved from PtdEtn and from other phospholipids seen in the negative ion profile, where the Cho phospholipids yield minimal response. As seen from the single ion mass chromatograms (Figure 13b) all the glycated species are found under the assigned glycated PtdEtn peak. The added glucosylated 16 : 0–18 : 2 GroPEtn (*m/z* 876), $[M-1]^-$ is easily detected in the single ion mass chromatogram (Figure 13c). Using this technique the levels of Glc PtdEtn in plasma have also been estimated[78] in diabetic and normal individuals to be 4.8% and 0.9% GroPEtn/total phospholipids respectively.

Normal-phase HPLC with on-line ESMS (LC/ESMS) is performed by splitting the HPLC flow by 1/50 resulting in 20 μL mL^{-1} being admitted to a Hewlett-Packard Model 5988B quadrupole mass spectrometer equipped with a nebulizer-assisted electrospray interface (HP 59987A).[36] Tuning and calibration of the system is achieved in the mass range of 400–1500 by using the standard phospholipid mix dissolved in the HPLC solvent A and flow-injected at 50 μL min^{-1} into the mass spectrometer. Capillary voltage is set at 4 kV, the endplate voltage at 3.5 kV and the cylinder voltage at 5 kV in the positive mode of ionization. In the negative mode, the voltages are 3.5, 3 and 3.5 kV, respectively. Both positive and negative ion spectra are taken in the mass range 100–1100 amu. The capillary exit voltage is set at 120 V in the positive and 160 V in the negative ion mode. For fragmentation studies the capillary exit voltage is raised to 300 V. Nitrogen gas is used as both nebulizing gas (40 psi) and drying gas (60 psi, 270 °C). Phospholipids, including the glucosylated diradylPEtn, are quantified on basis of standard curves established for each phospholipid class and for the oxidized phospholipids (core aldehydes, hydroperoxy and isoprostanes). The oxidized phospholipids that are used as standards are prepared as previously described.[36] The detection limit for Glc PtdEtn using normal scanning range (400–110 amu) is 20–30 pmol and the response is linear to 100 nmol. The equimolar ion intensities of different species of each phospholipid class varied by less than 5% in each of the ion modes.[99] The LC/ESMS response to different phospholipid classes varied greatly and required the regular use of standards.

5.1.2 Red Cells

Recently, the glycation products of the PtdEtn have also been identified as components of red blood cells.[78] Although PtdSer is present in large amounts, glycated PtdSer was not isolated. The various phospholipid classes and molecular species possess characteristic lipoprotein and cell membrane distribution. As in plasma, the complex lipid mixtures present in the red cells require chromatography and MS for complete determination of the structure. Figure 14 shows the separation of both glycated and nonglycated aminophospholipids from red cells incubated with glucose.[22] The glycated species represent the distribution found in the nonglycated fraction indicating a random glycation process towards both alkenylacyl, diacyl and alkylacyl species. The levels of Glc Etn in diabetic patients (4.8% glycated GroPEtn/total phospholipids) were found to be three times higher than normoglycemic individuals. The levels of glycated Etn have been recently measured by Fountain et al.[106] by acid hydrolysis of the red cell lipid extract and detection of the glycated Etn head group by GC/MS after reduction by $NaBH_4$.

5.1.3 Atheroma

Figure 15 shows the total negative ion current profile (Figure 15a), the single ion chromatograms for major species (Figure 15b), and the mass spectrum averaged over the elution time (15.01–15.89 min) of the glycated Etn phospholipid peak (Figure 15c) as obtained by normal phase LC/ESMS for a total lipid extract of an atherosclerotic plaque from a diabetic male.[98] In order to increase the sensitivity of detection, the scanning is limited to the mass range of 850 to 1000 amu, which eliminated any overlap with the PtdEtn, PtdCho + Cl and SM + Cl ions also present in the total negative LC/ESMS profile. As a result, only the dimers of the molecular species of lysoPtdCho remained visible. There is considerable discrepancy between the glycated and nonglycated sets of species excluding direct in situ interconversion, and suggesting possible deposition of these lipids from the circulation. The composition of the molecular species of the Etn phospholipids of the atheroma also differs significantly from that of human LDL (Table 5), with the relative proportion of the polyunsaturated PtdEtn and specially PlsEtn species being reduced. The most abundant glycated PlsEtn species in the plaque is the 38:4 (*m/z* 928). The possibility of selective glycation and/or oxidation is indicated by the absence of glycated PtdSer species, even though PtdSer species are detected in the atheroma. In samples analysed from nondiabetic individuals we found 2.4 nmol glycated diradyl GroPEtn per milligram of total lipid representing 1.3% of the total atheroma phospholipid. The atherosclerotic tissue from diabetics contained 11.5 nmol glycated diradyl GroPEtn per milligram of total lipid representing 7.3% of total atheroma phospholipid, while an analysis of normal aortic

Figure 15 Identification of glycated diradyl GroPEtn from atherosclerotic tissue of a diabetic male.[98] (a) Total negative ion current profile (mass range set to 850–1000 amu); (b) single ion plots of the major glycated diradyl GroPEtn; (c) averaged spectra from the glycated diradyl GroPEtn peak (15.01 to 15.89 min). Peak identification is given. LC/ESMS as described in Figure 13.

tissue did not show any PtdEtn glycation. These results are comparable to the levels of glycated PtdEtn previously measured by our group in plasma of diabetic individuals (4.8% glycated diradyl GroPEtn/total phospholipid).[78]

5.2 Oxidized Glycerophospholipids

5.2.1 Plasma Lipoproteins and Red Cells

It has been claimed that oxidative reactions in vivo are associated with pathological events. To this end much attention has been focused on the products of free radical damage in vivo. Since phospholipids are an abundant source of polyunsaturated FAs, the products of phospholipid oxidation can be markers of peroxidative damage. Ravandi et al.[99] have established an LC/ESMS system for the identification of hydroperoxides of the glycerophospholipids, their aldehyde esters, as well as their isoprostane esters. Figure 16 shows the separation of oxidized phospholipids of human LDL on a normal phase silica column, which allows the identification and quantification of PtdCho oxidation products. It is seen that the various oxidation products are well resolved from the residual Cho-containing phospholipids. Interestingly, the oxidation of PtdCho is accompanied by an extensive release of lysoPtdCho. The isoprostanes are produced only from the arachidonate-containing species. The oxidation products of other long chain polyunsaturated esters were not identified. The relatively saturated SM does not appear to be affected by mild oxidation with copper.[99] Ahmed et al.[107] have successfully extended this method to the identification and quantification of the lipid peroxidation products of human HDL resulting from treatment with peroxynitrite. Lynch et al.[108] have previously demonstrated the formation of the hydroperoxides and isoprostanes in plasma and LDL exposed to oxidative stress in vitro, but these workers did not analyze intact lipid esters.

Most of the efforts in phospholipid oxidation have been focused on PtdCho and PtdEtn. One technique for the quantitation of PtdCho hydroperoxides has been the use of HPLC with a chemiluminescence detector. Akasaka et al.[109] have developed an automatic method for the determination of hydroperoxides by injection of deproteinized plasma sample on to a reverse-phase column and subsequent introduction into two analytical columns and post-column reaction with diphenyl-1-pyrenylphosphine. They reported the presence of 6–7 pmol of PtdCho hydroperoxides in human plasma. The drawback of this technique is the complicated chromatography apparatus and the lack of detailed information about the molecular species of the phospholipid.

5.2.2 Atheroma

Ravandi et al.[110] have demonstrated the presence of hydroperoxides, core aldehydes as well as isoprostanes of glycerophospholipids in samples of atheroma. Figure 17

Figure 16 LC/ESMS analysis of oxidized PtdCho in oxidized LDL.[106] (a) Total positive ion current profile of oxidized LDL; (b) single ion plots of representative PtdCho oxidation products. Peak identification is given. LDL was oxidized by incubation with 5 μM $CuSO_4$ in 0.1 M PBS for 12 h at 37 °C. The total lipid extract of the oxidized LDL was dissolved in chloroform–methanol (2 : 1, v/v) and 20 μL of the sample containing 10 μg lipid was analyzed. Structural assignments for aldehydes and hydroperoxides are according to reference standards. Ions 832 and 830 were identified on the basis of retention time and molecular weight. (Reproduced with permission from Ravandi et al.[99])

Figure 16 (*Continued*)

shows appropriate single ion chromatograms. The adoption of the single ion monitoring mode allowed the detection limit to be lowered to 10–50 fmol for the different oxidized phospholipid classes.

5.3 Phosphoinositide Glycans

Over 100 glycosyl PtdIns anchored proteins have been described and a number of comprehensive reviews have appeared.[11,13] The anchors have been isolated in the free form and more commonly covalently bound to proteins, from which they may be released by chemical and enzymatic methods.

5.3.1 Plasma Lipoproteins

Although both phospholipases C and D specific for PtdIns glycans have been isolated from plasma, neither free nor bound PtdIns glycans have been detected in plasma or serum,[13,111] and the role of the enzymes has remained obscure. Recently, Nazih-Sanderson et al.[112] have shown that HDL_3 signaling in $HepG_2$ cells involves glycosyl-PtdIns-anchored proteins. In the presence of protease-inhibitors, HDL_3 releases in the culture medium several proteins with a residual inositolphosphoglycan that binds Ab_{IPG} after sodium dodecyl sulfate polyacrylamide gel electrophoresis analysis and immunoblotting. Thus, HDL_3 activates PtdCho hydrolysis through a multistep pathway involving the cleavage of glycosyl PtdIns-anchored proteins.

5.3.2 Red Cells

The nature of the lipid moiety of the glycosyl PtdIns anchor of the red cell acetylcholine esterase

Figure 17 Single ion monitoring LC/ESMS analysis of oxidized phospholipids in human atheroma.[110] Peak identification is given. Ald, core aldehyde. LC/ESMS conditions as in Figure 16.

has been determined[33,58] by GC/MS of lipid derivatives from hydrolyzed material and/or FAB/MS of the PtdIns or diradylglycerol moieties, released by nitrous acid deamination and PtdIns-specific phospholipase C treatment,[12,13,113] respectively. Phospholipid fragments may be generated from a glycosyl PtdIns anchor also by phospholipase D cleavage. The PtdIns anchor specific phospholipase D found in mammalian (including human) serum, cleaves the anchor irrespective of inositol acylation to give PtdOH.[13,114] Nitrous acid treatment of the anchor results in deamination of glucosamine residue and cleavage of glucosamine-inositol glycosidic bond to release an inositol-containing phospholipid fragment.[13]

The lipid moieties of the PtdIns anchor of the human red blood cell acetylcholine esterase are made up largely of alkylacyl species.[33] The human red cell acetylcholine esterase contains an additional FA (palmitate) on the inositol ring.[12] The molecular species of the PtdIns moiety of the acetylcholine esterase anchor have been identified and quantitated (mol%) as follows: 18:0′–18:0 (6.3%); 18:1′–18:0 (2.7%); 18:0–20:4(n-6) (<2.0%); 16:0′–22:4(n-6) (2.0%); 17:0′–22:4(n-6) (1.4%); 18:0′–22:4(n-6) (32.4%); 18:1′–22:4(n-6) (14.2%); 18:0′–(22:5(n-3) and 22:6(n-3)) (25.2%) and 18:1′–(22:5(n-3) and 22:6(n-3)) (11.0%). (The alkyl chains have been identified by primes). The values for the *sn*-1,2- and *sn*-1,3-isomers which were generated by acetolysis were summed. This human red cell acetylcholine esterase anchor is a plasmanylinositol that is palmitoylated on the inositol ring.[12] The early mass spectrometric studies on glycosyl PtdIns glycans have been performed with fast atom bombardment mass spectrometers, which have provided evidence for the presence of a palmitoyl group on one of the inositol hydroxyl groups in the PtdIns moiety of the glycosyl PtdIns anchor of the acetylcholine esterase.[12]

Neither FAB/MS/MS nor ESMS/MS can provide the molecular species composition of the glycosyl PtdIns anchors as long as deacylated materials are being used for the analysis.

6 CONCLUSIONS

The great complexity and the large number of phospholipid classes and molecular species continue to provide a challenge to the best contemporary methods of lipid analysis. Solvent extraction and TLC remain basic techniques for sample preparation, while HPLC on normal- and reversed-phase columns provide effective means for sample purification and preparation of standards.

Traditional sample extraction by liquid–liquid partition is time-consuming and involves large volumes of solvents. More effective is liquid–solid extraction, which is accomplished by passing a dilute plasma or red cell lipid extract through a solid adsorbent bed. However, in the absence of a simple and inexpensive detector for monitoring the column effluents many of these advantages are lost. The experimenter is forced to work blindly (or employ TLC for assessing the success of the SPE) and spend many hours and increasing volumes of solvent in trial and error.

The availability of combined chromatographic and soft ionization mass spectrometric or tandem mass spectrometric methods provide new, rapid and highly specific assays of lipid class and molecular species identification and quantification. In many instances repetition of the older quantitative work by the newer methods would be clearly justified and a revision warranted of much published data of lipid class and molecular species composition of many tissues and cells. Finally, the great potential of NMR as a quantitative tool of phospholipid class analysis remains to be generally exploited.

PAF	Platelet Activating Factor
PGE_1	Prostaglandin E_1
PlsEtn	Alkenylacyl Glycerophospho-ethanolamine
PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
PtdGro	Phosphatidylglycerol
Ptd_2Gro	Diphosphatidylglycerol
PtdIns	Phosphatidylinositol
PtdIns P	Phosphatidylinositol Phosphate
PtdOH	Phosphatidic Acid
PtdSer	Phosphatidylserine
SM	Sphingomyelin
SPE	Solid-phase Extraction
TBDMS	*tert*-Butyldimethylsilyl
TLC	Thin-layer Chromatography
TMS	Trimethylsilyl
UV	Ultraviolet
VLDL	Very Low Density Lipoprotein

Molecular luminescence spectroscopy, including fluorescence, phosphorescence, and chemiluminescence (CL), is among the most sensitive of analytical methods. Its use in clinical chemistry has been extensive since the late 1950s and is constantly expanding. Modern separation and immunoassay methods coupled with luminescence detection have revolutionized the detection and determination of endogenous substances, xenobiotics, and their metabolites. Newer techniques such as time-resolved fluorimetry and phosphorimetry, detection by fiber-optic sensors, and derivatization with infrared (IR)-emitting dyes are expanding the range of clinical analysis into new realms of analytical selectivity, sensitivity, and expediency on a scale unimagined until recently. This article considers some of the aspects of fluorescence, phosphorescence, and CL spectroscopy that have contributed to important recent advances in clinical analysis.

1 INTRODUCTION

Fluorescence spectroscopy and the closely related areas of phosphorescence spectroscopy and CL spectrometry have become firmly established and widely employed techniques in clinical analytical chemistry. Fluorimetry and CL spectrometry are now routinely used in the detection, quantitation, identification, and characterization of inorganic and organic compounds and of biological structures and processes. Phosphorimetry, although somewhat less popular, has the potential to be as useful as the other two areas if problems associated with sampling can be overcome.

Not long ago, it appeared that luminescence spectroscopy had reached an impasse as an area of active interest in clinical analytical chemistry. Luminescence spectra lacked the information content of, say, mass spectra or nuclear magnetic resonance spectra and quantitative measurements were dramatically influenced by contaminants in solution. Coincident spectra from analytes with nearly identical fluorophores (e.g. catecholamines) made multicomponent analysis nearly impossible.

CL analysis was based on very few luminescent molecules and derivatization of analytes with these luminophores was a major problem. Phosphorescence spectroscopy required the use of very low temperatures. The use of narrow-bore cylindrical quartz tubes (square cells crack at the joints in the freeze–thaw cycle) as cells for phosphorimetry entailed major difficulties with cleaning and filling and also with repositioning for reproducible measurements.

In the past three decades, much of this has changed. Thanks to recent advances in instrumentation and in new techniques, fluorescence and CL spectroscopy can be routinely applied to real analytical problems. In liquid chromatography and immunoassay, fluorescence introduces ultrasensitive detection to extremely selective separation methods. CL spectrometry can also often be coupled with the selectivity of the immune response to allow sensitive quantitation, often without chemical or physical separation of the analyte from an extremely ''dirty'' matrix. CL techniques are also valuable owing to their sensitivity (attomole and subattomole detection limits), their speed (a signal can be generated in a few seconds), their stablity (in some cases signals last for several hours), their relatively uncomplicated procedures, and their use of nonhazardous reagents.

With modern spectroscopic instrumentation, several analytes having nearly identical fluorescence spectra can often be determined simultaneously by taking advantage of differences in their fluorescent decay times or differences between the phase angles in their excitation and emission spectra rather than between their fluorescence spectral band intensities. Phosphorimetry, on the other

hand, seems to be advancing at a slower pace than the other branches of luminescence spectroscopy, although the observation of phosphorescence (albeit weak in intensity) at ambient temperatures on solid surfaces and in micellar solutions shows some promise. Moreover, the microsecond to millisecond duration phosphorescent emissions of some lanthanide chelates, notably those of europium(III) and terbium(III), can be intense and both their intensity and temporal characteristics have been used in clinical analysis.[1,2]

In this article, several modern aspects of luminescence spectroscopy are considered, especially as they pertain to clinical analysis of endogenous substances and of drugs and their metabolites. It is assumed that the reader already has some familiarity with the photophysical, photochemical, and instrumental fundamentals of these spectroscopic methods.

2 DIRECT FLUORIMETRY, PHOSPHORIMETRY, AND CHEMILUMINOMETRY

The systematic study of the production of light by electronically excited molecules is known as fluorescence, phosphorescence, or CL spectroscopy or collectively as luminescence spectroscopy. Luminescence processes can be classified according to the origin of the excitation energy in photoluminescence. In what is usually called fluorescence and phosphorescence, excitation occurs via the absorption of light by a potentially luminescent molecule. CL, on the other hand, entails excitation as the result of an energetic chemical reaction, almost invariably an oxidation reaction.

The simplest way in which to carry out luminescence spectroscopy is by direct photoexcitation or reaction of the analyte to be quantitated. However, if the analyte is not intrinsically fluorescent or phosphorescent, or if it does not form a luminescent product by direct oxidation, more complicated indirect methods entailing chemical derivatization or energy transfer may be necessary. These will be considered in the next section. Owing to its experimental simplicity, most luminescence methods entail measurement of the fluorescence of organic compounds of clinical chemical interest in which the excitation energy is provided by the absorption of visible or ultraviolet (UV) light.

Fluorescent methods comprise the great majority of the ultrasensitive assays carried out by light envision spectroscopy in the clinical sciences. However, in recent years there has been considerable interest in phosphorescence and in CL. Accordingly, these subjects will also be considered here.

Luminescence spectroscopy is used more often in quantitative analysis than in any other application. The quantitative relationship between fluorescence intensity, F, and analyte concentration, C, derives from the Beer–Lambert law (Equation 1):

$$I = I_o 10^{-\varepsilon cl} \tag{1}$$

where I and I_o are the intensities of exciting light transmitted through and incident upon the sample, respectively, l is the pathlength of light through the sample and ε is the molar absorptivity of the molecular species of interest at the nominal wavelength of excitation. The intensity of light absorbed, I_a, is given by Equation (2):

$$I_a = I_o - I_o 10^{-\varepsilon cl} \tag{2}$$

If all molecules that absorb light fluoresced, I_a would be the intensity of fluorescence. However, only the fraction, ϕ_f (the quantum yield of fluorescence), fluoresces. The remaining fraction returns to the ground state by nonradiative means. Hence (Equation 3):

$$F = \phi_f I_o (1 - 10^{-\varepsilon cl}) \tag{3}$$

The exponential term of Equation (3) can be expanded in a Maclaurin series so that (Equation 4):

$$F = \phi_f I_o \quad (2.3\varepsilon cl) - \frac{(2.3\varepsilon cl)^2}{2!} + \frac{(2.3\varepsilon cl)^3}{3!} - \cdots \tag{4}$$

If the absorbance (εcl) of the sample is <0.02, then to within 2.3% error, Equation (4) becomes the linear Equation (5):

$$F = 2.3 f \phi_f I_o \varepsilon cl \tag{5}$$

It then remains only to prepare a standard solution of concentration C_s and having fluorescence intensity F_s to be compared with the unknown solution of concentration C_u and fluorescence intensity F_u according to Equation (6):

$$C_u = \frac{F_u}{F_s} C_s \tag{6}$$

However, it is generally prudent to prepare a calibration curve for several standard solutions to check the linearity of the F versus C curve, before attempting the simple relative fluorimetry expressed in Equation (6) for a large number of samples.

In the case of phosphorescence, the measured intensity, P, is related to the concentration of analytes following similar lines of reasoning applied to fluorescence, according to Equation (7):

$$P = \phi_{st} \phi_p I_o (1 - 10^{-\varepsilon cl}) \tag{7}$$

Table 1 Drugs that exhibit direct CL

Analyte	Method[a]	Limit of detection	Range	Refs.
Tetracycline	Reaction with bromine in alkaline medium, FIA	19 μg mL^{-1} (4×10^{-5} M)	5×10^{-5}–1×10^{-2} M	4
Acetaminophen	Reduction of cerium(IV), FIA	0.070 μg mL^{-1}	1.00–10.0 μg mL^{-1}	5
Isoniazid	Oxidation with *N*-bromosuccinimide	0.024 μg mL^{-1}	0.050–20.0 μg mL^{-1}	6
Morphine	Reaction with permanganate, FIA, HPLC	0.7 pg (2 fmol, 1×10^{-10} M) for FIA 25 ng mL^{-1}, 50 ng mL^{-1} (aqueous solution, biological fluids) for HPLC	50 ng mL^{-1}–500 μg mL^{-1}	7, 8
Loprazolam	Reaction with permanganate, FIA	163 ng (7×10^{-6} mol/50 μL)	1×10^{-5}–1×10^{-3} M	9

[a] FIA, flow injection analysis; HPLC, high-performance liquid chromatography.

where ϕ_{st} and ϕ_p are the quantum yields of intersystem crossing (the fraction of excited molecules radiationlessly converted from the lowest excited singlet state to the lowest triplet state) and phosphorescence (the fraction of molecules arriving in the lowest triplet state that are deactivated by phosphorescence), respectively. As for fluorescence, Equation (7) can be expanded and for weakly absorbing solutions can be made analogous to Equation (6) according to Equation (8):

$$C_u = \frac{P_u}{P_s} C_s \tag{8}$$

where P_u and P_s are the phosphorescence intensities of the unknown and standard samples, respectively. Equation (8) is, therefore, the basis of simple quantitative phosphorimetry.

CL does not depend at all on the intensity of the exciting light as no photoexcitation occurs. Rather, the intensity of light emission observed from a chemi-excited luminescence process (I_{CL}) in which one of the direct products of the reaction fluoresces is governed by the efficiencies of the chemical reaction leading to the luminescent product (ϕ_c), formation of electronically excited molecules in the chemi-excitation process (ϕ_e), and fluorescence of the chemi-excited product (ϕ_f) as well as the rate at which the analyte is consumed in the chemiluminescent reaction (d[L]/dt) (Equation 9):

$$I_{CL} = \phi_c \phi_e \phi_f \left(-\frac{d[L]}{dt} \right. \tag{9}$$

If the CL reaction conditions are controlled so that it is carried out as pseudo-first-order disappearance of L, then (Equation 10):

$$-\frac{d[L]}{dt} = k_L[L] \tag{10}$$

where k_L is the pseudo-first-order rate constant for consumption of L. We then have Equation (11):

$$I_{CL} = \phi_c \phi_e \phi_f k_L[L] \tag{11}$$

which is linear in [L] and if the chemiluminescent reaction is carried out for a solution containing a standard concentration of L ($[L]_s$) an unknown concentration of L ($[L]_u$) can be determined from Equation (12):

$$[L]_u = [L]_s \frac{I_{CLu}}{I_{CLs}} \tag{12}$$

where I_{CLu} and I_{CLs} are the CL intensities of unknown and standard samples, respectively, after allowing both reactions to proceed for the same period of time.

There are two broad categories of luminescence analysis, namely direct and indirect. The direct luminescence method uses the native luminescence of the analyte and is limited to (but not all inclusive of) those molecules containing aromatic rings or highly conjugated aliphatic systems. The fluorescence of proteins, for example, is due almost entirely to emissions from phenylalanine, tyrosine, and tryptophan. Compensating for the lack of universality of the directly excited luminescence is the specificity and great sensitivity of analysis resulting from the luminescence properties inherent to the analyte of interest.

An example representative of direct fluorimetric analysis is the assay of lysergic acid diethylamide (LSD). LSD is highly fluorescent with excitation maximum at 325 nm and emission maximum at 445 nm. Direct fluorimetric estimation of LSD in tissues can determine as little as 3 ng of the compound per gram of tissue.[3] Table 1 gives several examples of drugs that can be analyzed using direct CL.

3 INDIRECT METHODS

Indirect fluorimetric methods are used for analytes that are weakly fluorescent or nonfluorescent. This approach

involves either the conversion of the analyte to a fluorescent derivative, using an appropriate reaction scheme, or the utilization of the capability of the analyte to influence (enhance or quench) the fluorescence of a fluorescent dye.

Conversion of the analyte to a fluorescent derivative can be achieved in several ways. Oxidation, for example, is used to convert phenothiazines into the corresponding sulfoxides, which are highly fluorescent.[10] Morphine can be analyzed fluorimetrically by oxidizing it to fluorescent pseudomorphine.[11] Dehydration of cardiotonic steroids with concentrated H_2SO_4 yields fluorescent products and this reaction has been used to develop several analytical methods for steroids.[12]

Some compounds can be converted to fluorescent derivatives by treating them with strong mineral acids. For example, morphine gives a highly fluorescent derivative after heating it in concentrated sulfuric acid.[13] The reaction product fluoresces when the solution is made alkaline. Codeine, when heated in concentrated sulfuric acid followed by making the solution alkaline, shows analytically useful fluorescence.[14] Chlorprothixene, a thioxanthene derivative used as a major tranquilizer, gives a fluorescent product in concentrated phosphoric acid.[15] Reserpine can be converted to a fluorescent derivative by treating it with nitrous acid.[16]

Weakly fluorescent or nonfluorescent primary arylamines[17] and arylhydrazines[18] can often be condensed with aldehydes or ketones to yield fluorescent derivatives. Aldehydes of analytical interest usually do not fluoresce. They may be condensed with arylhydrazines, such as naphthylhydrazines, or arylamines to yield fluorescent products. A general fluorimetric procedure for assaying primary amines using fluorescamine reagent has been developed.[19,20] Fluorescamine is a high-sensitivity fluorogenic reagent that reacts directly with primary amines to form fluorophores. *o*-Phthalaldehyde and its benzolog 2,3-naphthalenedialdehyde have also been used extensively to form fluorescent azine condensation products with analytes having primary alkylamino groups.[21]

Chelation of the analyte with certain metal ions yields analytically useful fluorescent chelates. For example, the magnesium chelates of tetracyclines are highly fluorescent and have been used for the fluorimetric analysis of tetracyclines.[22]

Analytes that have cationic groups can interact with water-soluble anionic fluorescent dyes, such as eosine, to form neutral complexes which will be extractable into low-dielectric organic solvents. Since the ionic dye will not be extracted alone into the organic solvent, the fluorescence of the extract will be a measure of the concentration of the cationic drug. For example, α-tubocurarine can be analyzed fluorimetrically after co-extraction into chloroform with the anionic dye Rose Bengal.[23]

Some nonfluorescent analytes may interact with fluorescent dyes and quench or enhance the fluorescence of the latter. The extent of quenching or enhancement can be quantitatively related to the concentration of the quencher. For example, halide ions such as Cl^- form precipitates with Ag(I). The adsorption of highly fluorescent fluorescein on the silver chloride particles quenches the fluorescence of the fluorescein and, consequently, can be used to quantitate Cl^-.[24]

The earliest use of the indirect CL method was made using the adenosine triphosphate (ATP)-dependent firefly system, which employs the enzyme firefly luciferase in a reaction that uses ATP and generates visible light. As little as 10^{-15} mol of ATP can be measured using the following firefly luciferase reaction[25] (Equations 13 and 14):

$$\text{ATP} + \text{luciferin} \xrightarrow[Mg^{2+}]{\text{luciferase}} \text{adenylluciferin} \qquad (13)$$

$$\text{adenylluciferin} + O_2 \longrightarrow \text{adenyloxyluciferin} + \text{light} \qquad (14)$$

This CL assay has had a huge impact in the medical community, especially in the fields of immunology and pathology. It has numerous applications because ATP is present in all living cells. This method has been used to measure intracellular ATP in bacterial cultures, allowing an estimate of bacterial growth. It has also been used to determine bacteriuria and the concentration of antibiotics in a serum specimen.[25–28] It is possible to investigate the growth and physiology of mycobacteria and filamental organisms, which are difficult to study using classical techniques.[25,29] The determination of ATP is also useful in the study of the ATP content of erythrocytes in various pathological situations.[30,31] It is used to study the critical effect of ATP and adenosine diphosphate (ADP) on platelet aggregation in vitro[32] and in monitoring of the release of ATP by platelets under the influence of thrombin.[33] It is used in studies regarding shape and lysis of erythrocytes[34] and it is helpful in determining the viability of stocked erythrocytes, leukocytes, and platelets.[35] Assessment of cell death,[36] evaluation of the viability of spermatozoa,[37] and monitoring of the leakage of ATP from erythrocytes during immunolysis are other applications of the CL assay of ATP using firefly luciferase.[38]

The indirect method has an advantage over the direct method in that, provided that a suitable reactant can be found to produce a fluorescent derivative, virtually any drug or metabolite having functional groups can be made amenable to fluorimetric analysis. However, it should be borne in mind that derivatization methods are most often applicable to classes of analytes rather than specific analytes and that the fluorescence of the derivative

usually arises from an electronic transition localized on the derivatizing reagent. As a result, the gain in generality of this method is partially offset by the sacrifice of selectivity. Moreover, because the derivatization reaction is invariably at least bimolecular, the maximum fluorescence intensity obtainable from the derivative will be limited by the concentration of the analyte, which at very low concentrations affects not only spectroscopic detectability but also the completeness of the derivatization reaction. The latter will generally decrease as the analyte concentration decreases. Consequently, indirect luminescence spectroscopy will, in many cases, be less sensitive than direct fluorimetry or phosphorimetry.

Up to the present, discussion has been confined to the determination of the absolute amount of metabolite recovered from a biological sample. However, the most elegant metabolic studies may entail the need for information about the relative fraction of drugs in true solution in the interstitial and intracellular fluids and bound to cellular and extracellular structures such as proteins, nucleic acids, and membranes. Some drugs containing aromatic rings demonstrate alterations in their luminescent properties, such as change in fluorescence efficiency upon passing from aqueous solution to a bound condition on cellular structures. The reason for the alterations of the luminescence properties of these compounds upon binding has been a subject of much research interest. Although it is generally conceded that changes in the intensity and energy characteristics of the fluorescences of these molecules upon binding are due to environmental effects, the specific nature of these effects is the subject of much controversy. Arguments involving viscosity, hydrogen bonding, environmental dielectric strength, and excited-state proton transfer have been invoked, but none of these alone adequately explains all of the observed effects. Nevertheless, the fact that the luminescence properties of drugs are altered upon binding may prove to be of substantial analytical value. For example, the dramatic increase in fluorescence efficiency that occurs in 8-anilino-1-naphthalenesulfonic acid upon binding to serum albumin forms the basis for the fluorimetric analysis of these proteins.[39]

Just as indirect fluorimetry and phosphorimetry entail the derivatization of nonluminescing analytes, CL can have an indirect mode in which derivatization is employed. In fact, owing to the paucity of molecules that demonstrate intense CL, it is often necessary to derivatize nonchemiluminescent molecules with standard intensely emitting chemiluminophores such as luminol (3-aminophthalhydrazide) or isoluminol (4-aminophthalhydrazide). These two CL molecules have been used most often as coupling to other molecules via their primary arylamino group often does not interfere with their CL properties.[40,41]

There is a whole class of chemiluminescent reaction partners which do not demonstrate CL directly. These are the dioxetanes[42] and their precursors such as bis(trichlorophenyl) oxalate (TCPO) and bis(2,4-dinitrophenyl) oxalate (DNPO), which are oxidized to dioxetanes by hydrogen peroxide, superoxide ion, and occasionally even molecular oxygen.[43,44]

The dioxetanes form electronically excited fragments when oxidized. However, in order to see analytically useful luminescence there must usually be present, in solution, a suitable energy acceptor that is also a good fluorophore. The acceptor, usually a fluorescein or rhodamine derivative, collects the excitation energy from the electronically excited dioxetane fragment and after thermal relaxation to the lowest vibrational level of its lowest excited single state, may emit the excess energy as fluorescence. The analyte is usually the oxidizer, an enzyme, or a metal ion catalyzing the oxidation, but may

Table 2 Drugs that can be analyzed using an indirect CL system

Analyte	Method	Limit of detection	Range	Refs.
Penicillin	Enhancement of luminol CL reaction, batch method	$100\,ng\,mol^{-1}$	$100\,ng\,mL^{-1}-100\,\mu g\,mL^{-1}$	45, 46
Cephalothin sodium	Enhancement of luminol CL reaction, batch method	–	–	47
Cortisone	Sensitization of CL of sulfite by cerium(IV), FIA	$0.040\,\mu g\,mL^{-1}$	$0.100-1.00\,\mu g\,mL^{-1}$	48
Hydrocortisone		$0.028\,\mu g\,mL^{-1}$		
Prednisolone		$0.016\,\mu g\,mL^{-1}$		
Methylprednisolone		$0.021\,\mu g\,mL^{-1}$		
Dexamethasone		$0.16\,\mu g\,mL^{-1}$	$0.500-5.00\,\mu g\,mL^{-1}$	
Betamethasone		$0.30\,\mu g\,mL^{-1}$		
Quinine	Sensitization of CL of sulfite by cerium(IV), FIA	$0.64\,\mu g\,mL^{-1}$	$5.00-500\,\mu g\,mL^{-1}$	49
Hydrocortisone	Solid-state peroxyoxalate CL, HPLC	$2\,ng\,mL^{-1}$	–	50
Digoxin		$2\,ng\,mL^{-1}$		
Theophylline		$4\,ng\,mL^{-1}$		

also be the fluorophore. The quantitative relationship between analyte concentration and CL intensity is similar to that in Equation (11) but now the efficiency of energy transfer is also included in the constant of proportionality.

Table 2 gives examples of drugs that can be analyzed using indirect CL.

4 LUMINESCENCE DETECTION IN CHROMATOGRAPHY AND OTHER SEPARATION METHODS

A major limitation of the application of luminescence spectroscopy to clinical analysis is the lack of specificity owing to the similarities in spectral band shapes and spectral positions of the luminescence spectra of many compounds. An obvious way to solve this problem is to separate the analytical sample's interfering constituents from each other prior to quantitation by luminescence. HPLC and related separation methods can be coupled to luminescence spectroscopy in order to take advantage of the sensitivity of the latter and the specificity of the former.

Luminescence affords a very sensitive and selective means of detection in flowing systems such as HPLC, electrophoresis, FIA, and flow cytometry.[51] HPLC fluorescence detectors are similar in operation to normal fluorimeters. Most fluorescence detectors use filters for crude monochromation. At somewhat greater cost, diffraction grating monochromated instruments are available specifically for HPLC. Filters generally pass light in a wider band than do the monochromators. This is often an advantage since the detector does not need to be specifically tuned for each compound as it is eluted. Filters favor spectral sensitivity because more light excites the sample and is collected by the detector. Grating monochromators favor selectivity, which is preferable depending upon the requirements of a specific analysis. For detectors used at concentrations where the absorbance at the excitation wavelength is <0.02, fluorescence intensity is linear with concentration. The fluorimetric detector is susceptible to the usual interferences which hinder fluorescence measurements, mainly background fluorescence and quenching.

In the operation of a fluorimetric HPLC detector the light from a UV or visible source is monochromated to some degree and focused on the cell which is on-line with and subsequent to the separation column. Fluorescence is emitted by the sample in all directions so that the emitted light can be measured with the detector at right-angles to the path of the exciting light and the direction of fluid flow. Stray or scattered excitation light is then blocked from the detector by a filter, and the intensity of the emitted energy is measured by a photocell. It is important to recognize that the solvent has a strong effect on the intensity of fluorescence. For instance, quinoline is nonfluorescent in hexane, but fluorescent in ethanol. The solvent also scatters light owing to the Raman effect. This light is of slightly lower energy than the exciting light. For this reason, the emission wavelength is selected to be longer than that of the scattered Raman light.

Flow cells have been designed which can be used for both fluorescence and absorption measurements. Quantitation can be considerably improved by simultaneously monitoring the absorbance and fluorescence signals, which extends the linear dynamic range for fluorescent samples. At high sample concentrations, where the absorbance at the excitation wavelength is >0.02, fluorescence intensity becomes nonlinear with concentration. At these higher concentrations, however, the light absorbance of the sample is often measurable and linear with concentration. Fluorescence, however, is often detectable at concentrations 10^3–10^9 times lower than those where absorbance is detectable. Fluorescence spectroscopy using flow cells in the chromatographic path and postcolumn with monochromated or filtered arc-lamp excitation sources has been applied to detection in HPLC for several decades and a wide variety of commercial detectors are currently on the market.

The laser, as an excitation source for luminescence detection in chromatography, has become popular because of its high excitation power and its highly focused beam. The laser, although many orders of magnitude more powerful than an arc lamp as an excitation source, has, so far, produced detectability only a few orders of magnitude better than that achieved with arc lamps. This is a result of high background luminescence produced by photo and thermal decomposition of solution components induced by the large energy output of the laser. Thermal lensing (changes in solution refractivity) also produces spectroscopic complications. On the other hand, the high degree of collimation of the laser beam has made it an excellent excitation source with the microbore cells and tubing used in capillary zone electrophoresis (CZE). A typical laser beam can be focused into a spot no more than a few micrometers in diameter. With laser excitation and fluorescence detection CZE, analyte amounts below 1 amol (at nanomolar concentrations) have been detected.

The advantages offered by the power and high degree of collimation of the laser as an excitation source can be exploited to measure the properties of a host of particles, including cells, algae, bacteria, and larvae, which either show native fluorescence or can form fluorescent adducts. A well-defined flow of isolated particles is achieved

by using hydrodynamic focusing. For this purpose, a sample flow is obtained within a larger ''sheath'' flow of different specific density, which allows flow of the sample cells into a well-defined part of the cuvette, where a laser excitation-based analysis is performed. The single cell passage is guaranteed by adjusting the two flows, hence collision between two cells (particles) is avoided. The method allows high-speed analysis of the cells and is called ''flow cytometry'' or ''fluorescent cell sorting''.[51]

CL has been coupled to HPLC with promising results.[52,53] However, the multitude of reagents required to generate CL, especially when energy transfer from the primary chemiluminescing molecule to a better fluorescing acceptor is required, necessitates the use of several pumping systems and a very complex, if not unwieldy, chromatographic system. Moreover, although HPLC (and FIA) provide CL spectrometry with a degree of specificity not inherent to the spectroscopic technique alone, the dynamic characteristics of the flowing separation systems reduce the residence time of the luminescing system in the detector. It is precisely the feature of ability to observe and integrate the CL signal over the entire course of the lumigenic reaction that gives CL its great sensitivity, although even static CL methods are often based on instantaneous measurements for the sake of expedience.

Detection of phosphorimetry in HPLC is an active area of current research interest but is not yet in routine analytical use. To date, much of the work in this area has centered on the use of biacetyl (2,3-butanedione) as a phosphorophore. This molecule is one of very few that phosphoresce in fluid solution at ambient temperatures although rigorous deoxygenation of the solvent is necessary to observe biacetyl phosphorescence. Emissions from phosphorophores such as quinoline entrapped in micelles or cyclodextrins,[54,55] to protect them from dissolved oxygen and, hence, quenching, have been observed but are inadequate for sensitive chromatographic detection. Phosphoresence efficiencies at room temperature tend to be low. A more promising approach is the use of a phosphorescent solute to provide a background phosphorescence which can be quenched by the analyte in the detector cell. Because organic molecules that phosphoresce in fluid solution at ambient temperatures have lifetimes of the order of milliseconds (fluorescent molecules have lifetimes of the order of nanoseconds), dynamic quenching of phosphorescence can be about a 10^6-fold more sensitive than that of fluorescence – so, in principle, although it is impossible to detect quenching of fluorescence at concentrations of lower than, say, 10^{-4} mol L^{-1}, quenching of phosphorescence can be detected at concentrations $> 10^{-10}$ mol L^{-1}.

5 FLUORESCENCE, PHOSPHORESCENCE, AND CHEMILUMINESCENCE DETECTION IN IMMUNOANALYSIS

Immunoassay methods have assumed a role of major importance in clinical analysis. Their ability specifically to quantitate analytes in biological fluids has proven invaluable in the field of biomedical analysis. Their low cost and amenability to automation and also to simple ''dipstick'' methods, coupled with their sensitivity and specificity, have often permitted the circumvention of tedious chromatographic methods in diagnostics.

Immunoassay derives from the ability of mammals to biosynthesize specialized water-soluble globular proteins (antibodies) to complex invasive materials (antigens). The number of molecules capable of eliciting antibody formation (immunogens) is vast, and comprises naturally occurring macromolecules or cells containing such macromolecules on their surfaces.

An antigen is any substance capable of reacting with an antibody but not necessarily capable of introducing antibody formation. Therefore, all immunogens are antigens, although antigens may or may not be immunogens.

Antibodies are a group of heterogeneous, structurally related proteins derived from B-lymphocytes and known as immunoglobulins (Igs), having molecular weights of 150 000–160 000 Da. Each Ig molecule contains two sites of binding which have variable amino acid sequences and appear to be responsible for the great specificity of binding common to antibodies. Binding of these sites by immunogens creates the molecular memory that converts the Igs to antibodies.

Antibodies developed in response to a given immunogen will recognize and bind to only a small section of the immunogen. The ability of a molecule to elicit antibody formation depends on its size. Molecules with molecular weights $< 10\,000$ Da are generally not immunogenic. However, an immunoresponse can be elicited by small molecules or haptens covalently coupled to macromolecules such as albumins or polypeptides. The antibodies produced may react with sites on the hapten even when the hapten is not coupled to the other carrier molecules.

Immunoanalytical methods arise from the competitive binding that occurs between a labeled and an unlabeled ligand for highly specific receptor sites on antibodies. The measurement of some physical or chemical property such as luminescence intensity associated with the label, as a function of unlabeled ligand (analyte) concentration, allows the construction of a calibration curve from which unknown ligand concentrations may be interpolated.

Distinction of the signal corresponding to either the bound or free labeled analyte from that of the total may sometimes be necessary or desirable. This may be

accomplished in two ways. The first involves physical separation of the antibody-bound fraction from the free fraction of labeled analyte. This can be accomplished by using a salt such as ammonium sulfate or a polymer such as poly(ethylene glycol), to precipitate the excess free antibody and analyte-complexed antibody, followed by centrifugation. Alternatively, solid-phase extraction, in which the analyte or antibody is attached to a solid surface (beads, tube wall, dipsticks, etc.) may be employed. Competition between reactants in the liquid phase for the complexant in the solid phase permits the physical separation of the labeled material in the two phases. These techniques are called heterogeneous immunoassays and are required in methods where the labels employed are difficult or impossible to distinguish when present as both free and antibody-bound labeled material. Homogeneous immunoassays, in which physical separation of bound from free labeled ligand is not required, constitute the second category. Signals which differ for the bound and free labeled ligands are obtained from the test solution which contains all the participating analytical species. If the label is a fluorophore, environmental effects imposed on specific label properties can lead to signal modification. For example, a polarization of fluorescence resulting from the increase in molecular volume associated with labeled ligand binding to antibody protein can be monitored. Alternatively, the partitioning of a fluorescent label into an antibody binding site from the bulk aqueous solution may shift, quench, or enhance its fluorescence.

Separation-free, homogeneous immunoassays offer several important advantages over heterogeneous methods. As no separation is involved, the time and cost required per assay is decreased. Additionally, since the physical transfer step is avoided, potential sample loss is reduced.

Fluorescence immunoassay entails the measurement of the fluorescence of a fluorescent label which is bound to an antigen or antibody engaged in competitive immunochemical binding and whose spectral properties vary with the state of complexation of the labeled entity. Fluorescent labels are used in homogeneous and heterogeneous immunoassay systems and may be bound to antigens, antibodies, or solid phases or they may exist free in solution as enzyme substrates.

For a fluorescent label to be used in homogeneous immunoanalysis, it should have certain attributes. As the fluorescence signal must often be measured in a partially opaque or light-scattering biological matrix, the label should have a high quantum yield of fluorescence. To minimize spectroscopic interferences the excitation and emission maxima of the probe should occur at wavelengths longer than those of the other components of the test solution. Excitation spectra of dilute serum, the most commonly tested matrix of biological origin, have excitation maxima at 280 and 340 nm and an emission maximum near 350 nm (also near 520 nm if bilirubin bound to albumin is present). For a fluorescent label to be useful in a serum solution it should emit at wavelengths longer than 400 nm or, even better, longer than 500 nm.

The most popular fluorescent labels for immunoassay have been those derived from the long-wavelength, strongly emitting xanthene dyes fluorescein and rhodamine B. The isothiocyanates or isocyanates of these fluorophores can label primary and secondary aliphatic amines in aqueous solutions. Consequently, they can be used to label a wide variety of analytes. Even those compounds which do not have indigenous alkylamino groups can often be labeled by introducing bridging groups (e.g. aminoethyl) which are amenable to coupling with the isothiocyanato or isocyanato functions.

Heterogeneous fluorescence immunoassay can be carried out with the aid of the separation procedures described earlier and may be desirable when there is not much distinction between the emissive properties of bound and free labels. Occasionally, a second antibody, directed at the antianalyte antibody, will be used in a ''double-antibody'' method to precipitate the bound labeled and unlabeled analyte or to alter the optical properties of the label in such a way as to make the analysis more sensitive. The assay of human chorionic gonadotropin, which forms the basis of most pregnancy tests, is carried out via a double antibody fluorescence immunoassay.[56]

Homogeneous fluorescence immunoassays can often be carried out even when there is no obvious change in the intensity of spectral position of fluorescence of the label upon binding to the antibody. If polymer films or nonlinear crystals are used to polarize the exciting light and then the fluorescence of the sample excited by polarized light is analyzed, it will usually be observed that the intensity of fluorescence reaching the detector will be lower from those samples in which a greater amount of antibody binding occurs. This is a result of the higher degree of polarization of the fluorescence emitted from the labels affixed to the slowly rotating macromolecular antibody. The polarized emission is more efficiently attenuated by the polarizing film whose optical axis is perpendicular to the plane of polarization of the fluorescence than is the unpolarized light emitted by the rapidly rotating, labeled analyte molecules which are not bound to macromolecules. This forms the basis of fluorescence polarization immunoassay (FPIA). The apparent decrease in fluorescence polarization with increasing analyte binding occurs as a result of decreasing labeled analyte binding and can be used to prepare a calibration curve from which the concentration of test samples can be determined when their polarized fluorescences are measured.

Although, in principle, it should be possible to use phosphorescent labels in immunoassay, in practice this is, with the exception of certain lanthanide chelates, not done. The principle reason for this is that in fluid, aerated solutions, very few molecules phosphoresce so that phosphorescence immunoassay as a simple, practical laboratory method would be difficult or impossible.

Ligand labeling with phosphorescent lanthanide chelates has created a form of phosphorescence immunoassay.[1,2] Some chelates of rare earth metals have unique emission characteristics in that upon excitation of aromatic portions of the ligands of the lanthanide complex, the energy of excitation is efficiently transferred to the lanthanide ion. This sensitizes f–f transitions localized on the metal ion which produce very narrow, almost line-like emission bands which arise from spin-forbidden transitions and which permit all of the emitted light to be collected by the detector with narrow emission slits. Eu(III) chelates give a red emission whereas Tb(III) chelates phosphoresce green. In addition, the rare earth chelates have very large Stokes' shifts, excitation usually being effected in the UV region. The excitation of these chelates is broad, which permits excellent sensitivity and selectivity by allowing the use of fairly wide bandwidths for excitation and narrow bandwidths for emission. With the proper combination of a rare earth chelate and a fluorimetric technique, sensitive immunoassays that avoid a large number of interferences can be developed.

CL immunoassay, a technique which is rapidly gaining popularity because of its great sensitivity (limits of detection of $\sim 1 \times 10^{-15}$ mol L^{-1} are sometimes attained), is in a sense a variation of fluorescence immunoassay.[57,58] CL manifests itself in the fluorescence of the oxidation products of some highly strained, highly reduced molecules (e.g. acridinium esters, peroxyoxalate esters, and amino-substituted cyclic hydrazides of phthalic acid). These oxidations are frequently catalyzed by metal ions and occur at appreciable rates only when the precursors of the species (the labels) and the oxidizers are freely diffusable in the solution (i.e. they will not generate light when bound to antibodies or perhaps prior to generation in an enzymic reaction). In this sense, they are analogous to many of the fluorescent labels. However, photofluorescence or photophosphorescence analysis entails the measurement of light emitted by a fraction of an even smaller fraction of molecules absorbing light for an instant. In CL it is possible to gather and integrate the light emitted in the chemiluminescent reaction over the entire course of the reaction. Consequently, very low detection limits can be attained if the chemiluminescent reactions have high luminescence efficiencies so that the choice of labels is much more restricted than in fluorescent immunoassay. Energy transfer to a strongly emitting secondary fluorophore from the originally chemi-excited product is sometimes a remedy for this.

6 TIME- AND PHASE-RESOLVED FLUORIMETRY

The fluorescence spectroscopy described so far is based upon the measurement of the intensity of fluorescence produced under "steady-state" conditions of excitation. "Steady-state" fluorimetry is derived from the excitation of the sample with a continuous temporal output of exciting radiation. The lamps and the power supplies used in conventional fluorimeters are sources of continuous radiation. After a short period of initial excitation of the sample, a steady state is established in which the rate of excitation of the analyte is equal to the sum of the rates of all processes deactivating the lowest excited singlet state including fluorescence. When the steady state is established, the observed fluorescence intensity becomes time invariant and produces the temporally constant signal which is measured by the photodetector. With the development of modern electro-optics however, it has become possible to excite a potentially fluorescent sample with a pulsed flash lamp which emits its radiation in bursts of 2–10 ns duration with about 0.2 ms between pulses. Pulsed lasers generate even shorter duration pulses (typically down to 1 ps). A fluorescent sample excited with such a pulsed source will not fluoresce continuously. Rather, its fluorescence intensity, excited by a single pulse, will decay exponentially until the next pulse again excites the sample. The fluorescence from the sample excited by the pulsed source can be represented, after detection, as a function of time on a fast sampling oscilloscope used in conjunction with a multichannel pulse analyzer. The former approach is called pulse fluorimetry and the latter time-correlated single-photon counting. In either case, fluorescences with decay times much longer than the lamp-pulse characteristics can be analyzed in much the same way as radioactive decay curves. A semilogarithmic plot of fluorescence intensity against time will yield a straight line (or a series of overlapping lines if several fluorophores have comparable but not identical decay times) whose slope is proportional to the decay time and whose vertical axis intercept can be compared with that of a standard solution of the fluorophore for quantitative analysis. If, however, the lamp pulse time and the decay time of the fluorophore are comparable, the lamp characteristics must be subtracted from the observed signal to obtain the fluorophore's decay characteristics. This is usually accomplished by using a computer to deconvolute the composite temporal characteristics of the lamp and the fluorophore output.

The pulsed-source (time-resolved) method effects spectroscopic distinction between the emissions of several fluorescing species by taking advantage of differences in their decay times rather than their fluorescence intensities. This means that several strongly overlapping fluorescences such as those of several proteins or catecholamines can be quantitated simultaneously without chemical or mechanical separation.

Phosphorescence can also be measured in a time-resolved mode. Because of the much longer lifetimes of phosphorescence (10^{-6}–10 s), much longer duration lamp pulses or even mechanical chopping of a continuous source for long-lived phosphorescence (0.1–10 s) can be used. As a result, time-resolved phosphorimetry is much less expensive and electro-optical factors much less demanding than time-resolved fluorimetry. Many of the assays carried out with the lanthanides Eu(III) and Tb(III) are excecuted as time-resolved phosphorimetric analysis.

The pulse-fluorimetric method is best used when one species has a much longer decay time than other species in the solution. It is much less useful when several species in solution have similar decay times. The pulse-fluorimetric approach has seen only limited application to the resolution of more than two fluorescers under any circumstances.

Time-resolved fluorimetry is also useful for the elimination of interferences from stray light due to Rayleigh and Raman scattering. The latter phenomena occur on a timescale of 10^{-14}–10^{-13} s and as they have a much shorter duration than lamp or laser pulses this light associated with them can be eliminated from the signal that ultimately reaches the detector. Time-correlated single-photon counting is superior in its ability to resolve multiple fluorescence from the same solution.

Phase fluorimetry is another useful fluorimetric technique for the determination of substances with overlapping fluorescence spectra. In phase fluorimetry the phase angle between the lamp pulse and the emission of fluorescent light allows discrimination between fluorescences of different origin. Phase-sensitive optics and electronics are rather complicated and, as in the case of time-resolved fluorimetry, will only be mentioned here in passing.

7 FIBER-OPTIC FLUORESCENCE SPECTROSCOPY

A fairly recent but very significant development in fluorescence instrumentation is seen in the fiber-optic fluorimeter. In this instrument a fiber-optic cable replaces the sample compartment and cell and a covalently bound flurophore and perhaps a chemically selective membrane at the distal end of the cable comprise a fluorescence sensor. This device has found extensive use in environmental and biological analysis. In the fiber-optic instrument, light from a xenon lamp, laser, or light-emitting diode (LED) travels along an optically conducting fiber to its distal end, where activation of a covalently bound fluorophore causes fluorescence. Fluorescence sensors based on direct fluorescence or competitive binding are available but most are based upon fluorescence quenching of the sensor fluorophore by the analyte.

The instrumentation consists of a light source, optical filters, the fiber-optic cable, a sensing zone (the fluorophore and auxiliary membranes or reagents) and a detector. Lasers, xenon, hydrogen, deuterium, mercury, and halogen lamps, and LEDs have been used as excitation sources. Fiber-optic fluorescence spectrometers may be operated in a continuous or pulsed excitation mode. The latter mode allows for the application of time-resolved fluorimetry. The material of which the optical fiber is made determines the excitation wavelength range used. Fused-silica, glass, and plastic fibers are the most common fiber materials. Silica can be used from the UV range down to 220 nm but the fibers are expensive. Glass is suitable for use in the visible region and is lower in cost than silica. Plastic fibers are even less expensive but are limited to use above 450 nm.

Fiber-optic sensors are less expensive, more rugged, and smaller than electrodes; in the future we may see the former replacing the latter in various areas of analytical and clinical chemistry. Fields of application include environmental monitoring, process control, remote spectroscopy in high-risk areas with radioactive, explosive, biological, or other hazards, titrimetry, and in vivo bioanalysis.[59,60]

8 SEMICONDUCTOR LASERS AND RED AND NEAR-INFRARED EMITTING LABELS

Semiconductor lasers (laser diodes) have recently appeared as luminescence excitation sources. They have several outstanding advantages over gas and dye lasers and arc lamps as excitation sources. They are more powerful and more coherent light sources than arc lamps. They also have the advantage of producing a polarized beam which can be useful for certain applications. They are smaller, more compact, and much less expensive than other kinds of lasers and the fact that most semiconductor lasers emit in the far-red or IR region means that less energy can be deposited in the sample so that considerably less thermal decomposition can occur than with conventional ion, excimer, and dye lasers. The

fact that emission from semiconductor lasers is largely confined to the far-red and IR region is a ''mixed blessing''. On the one hand, the fact that so few substances demonstrate electronic absorption in that region of the electronic spectrum means that excitation of semiconductor laser light will be very selective. For example, the often interfering luminescences of tryptophan and bilirubin from serum samples will not be problematic with semiconductor laser excitation because these substances are not excited by red light. On the other hand, since so few substances absorb red light, a new generation of fluorescent probes and labels is required for the labeling of analytes to be detected subsequent to chromatographic or immunochemical analysis.

Several of the polymethine dyes absorb in the red, far-red and near-infrared (NIR) region and fluoresce efficiently also in this spectroscopic region. Functional derivatives of these may provide excellent fluorescent labels for semiconductor laser excitation. Several research groups are currently involved in the synthesis and development of large polyunsaturated dye molecules which are excited and show luminescence in the red and NIR region. This promises to be one of the most exciting areas of luminescence spectroscopy for the foreseeable future.

ABBREVIATIONS AND ACRONYMS

ADP	Adenosine Diphosphate
ATP	Adenosine Triphosphate
CL	Chemiluminescence
CZE	Capillary Zone Electrophoresis
DNPO	Bis(2,4-dinitrophenyl) Oxalate
FIA	Flow Injection Analysis
FPIA	Fluorescence Polarization Immunoassay
HPLC	High-performance Liquid Chromatography
Ig	Immunoglobulin
IR	Infrared
LED	Light-emitting Diode
LSD	Lysergic Acid Diethylamide
NIR	Near-infrared
TCPO	Bis(trichlorophenyl) Oxalate
UV	Ultraviolet

Planar chromatography (PC) like any other chromatographic technique is a multistage distribution process. It is a form of liquid chromatography in which the stationary phase is supported on a planar surface rather than a column. Separations in PC occur because of differential migration velocities through the sorbent layer in a fixed separation time. The sample zones are fixed in space at the completion of the separation, allowing off-line monitoring. There are two planar techniques: paper chromatography and thin-layer chromatography (TLC). In recent years, TLC has superseded paper chromatography owing to greater speed, versatility, and reproducibility. Improvements in techniques and equipment as well as the ready availability of high-quality plates with uniform layers have extended and increased the use of TLC in clinical chemistry and other disciplines, offering quantitative as well as qualitative analysis. High-performance thin-layer chromatography (HPTLC), in particular, has developed to the extent that separation and quantitation can provide results that are comparable with other analytical methods such as high-pressure liquid chromatography (HPLC). The widespread application of TLC is also due to the fact that it is simple, robust, and flexible, and has a large sample throughput. Furthermore, coupled spectroscopic methods (TLC/mass spectrometry (TLC/MS), TLC/Fourier transform infrared spectrometry (TLC/FTIR) etc.) have considerably enhanced the reproducibility of TLC.

TLC is often critically compared with column chromatography such as HPLC. This is a matter of endless dispute. Each technique has its own advantages and limitations. TLC is only inexpensive when qualitative results are needed. When reliable quantitative data are required, TLC is as expensive as column chromatography. In the authors' opinion, complementary rather than competitive chromatography offers the best solution to analytical requirements.

1 INTRODUCTION

PC was developed in the late 1950s. PC means chromatography in a thin planar stationary field with a length to thickness ratio often exceeding 1000 : 1. It is a physicochemical separation method, in which components to be separated are distributed between two phases. One of these phases consists of a flat stationary bed of large surface area, and the other is a mobile phase that migrates through the stationary phase by capillary action or under the influence of forced flow. Forced flow is achieved by pressure, by an electric field, or by centrifugal force. The movement of the analyte is expressed by its retardation factor (R_f), which is the ratio of the distance moved by the analyte from the origin to the distance moved by the flowing solvent from the origin. Each analyte will have its own R_f value. Thus, the sample zones are fixed in space at the completion of the separation, allowing off-line monitoring.

Initially, paper chromatography was the only planar chromatographic method but TLC has superseded paper chromatography. The use of TLC for separation and quantitative determination of a wide variety of organic and inorganic substances has considerably increased. This increase is due to improved instrumentation for spotting, developing, and scanning layers and for applying detecting reagents. In addition, development of optimization strategies and special techniques, such as scanning of radioactive zones and TLC coupled with spectrometry (TLC/MS, TLC/FTIR, etc.) have enhanced the analytical capabilities of TLC. TLC is considered to be an ideal chromatographic method for clinical laboratories. It is used clinically as an aid in diagnosis.The advantages of TLC over the other methods include simplicity, rapidity, versatility, applicability to a large number of samples in minimal time, and low cost in terms of reagent and equipment. Owing to these advantages, this method of analysis is preferred in clinical chemistry. Several comprehensive texts[1–9] are now available on the PC technique. The attempt here is to not to replace the existing reviews and books available on the subject but to outline recent progress in this area.

2 PRACTICAL CONSIDERATIONS

In this section, the basic steps involved in the analysis of biological samples by PC are discussed.

2.1 Specimen Collection and Storage

Many biological specimens can be used for determination of various analytes. These include whole blood, plasma, serum, urine, saliva, cerebrospinal fluid, gastric fluid, amniotic fluids, body tissues, and so on. Each type has advantages and limitations with respect to its availability, ease of collection, and the amount of information that can be obtained from its analysis. Plasma, serum, and urine samples are most often used in clinical laboratories. Quality control (QC) in the clinical laboratory begins before the sample is collected from the patient. Sample collection is a crucial element in the process of patient diagnosis and treatment. It is important to ensure that a proper and appropriate sample is being collected as the validity of the test results is dependent on the integrity of the specimen.[10,11] All specimens should be collected in a clean sterile unbreakable leakproof bottle. The bottles should be properly stoppered, sealed, and labeled with patients' names, date, and time of collection. To promote clot formation and minimize the potential for hemolysis in blood samples, specimens should be maintained in an upright position and agitated as little as possible during transportation.

Biological specimens for substance-abuse testing programs and forensic purposes must be handled with great care as they can be tampered with by substitution, dilution, or adulteration. In such cases, specimens should be collected under close supervision and transported under custody to avoid pilferage.[10–15]

Proper storage and preservation of samples are also important in clinical chemistry.[10,11] When the samples cannot be analyzed immediately, the collected samples may either be stored at 2–4 °C or for longer periods at −20 °C to −70 °C until analysis. This will, however, depend on the substance to be analyzed. Moreover, some blood and urine samples may need acid, alkali, or solvent stabilization. If samples are left at room temperature for long prior to analysis, their pH changes and they begin to decompose, leading to erroneous results. Long-term storage also enhances the probability of degradation of drugs and metabolites in biological samples. Ideally, prompt delivery of the collected samples to the laboratory and a short period of storage increase the validity of test results. It is also important that samples should be protected from direct light and heat during transportation and storage, and they should, therefore, be kept cold during transport, preferably in an insulated box containing ice or some other cooled packing.

2.2 Sample Preparation

Biological samples are very complex multicomponent mixtures of organic and inorganic compounds in which the specific target analyte is found in minute amounts. Therefore, selective isolations of analytes from the samples and preconcentration procedures are often required prior to analysis. Purification and concentration steps enrich the analyte in the sample so that it falls within the detection limit of the analytical technique employed. Considerable literature on sample preparation exists and has been reviewed.[11,16–22]

The choice of the cleanup procedure may depend on the technique used for detection and determination, the detection limit required, and the speed of analysis and recovery. Sometimes combinations of procedures are used. In this section, frequently used sample preparation procedures are discussed.

Dilution is a very simple and effective means of sample preparation. It is nonspecific and is used where an analyte is present in a sufficiently large concentration. The sample is diluted with water or buffer, centrifuged if needed to remove particulate matter, and then assayed.

Another effective method of sample preparation is precipitation and deproteinization. This is often used on plasma and whole blood samples prior to analysis. The agents commonly used to precipitate proteins are either

acids (viz. trichloroacetic acid, perchloric acid, tungstic acid, sulfosalicyclic acid, and metaphosphoric acids, etc.), organic solvents (methanol, ethanol, acetone, acetonitrile, and dimethyl sulfoxide), inorganic salts (ammonium sulfate) or any metal cations (zinc and copper). The technique is simple and rapid. The main disadvantage of this method is that there may be loss of the analyte by occlusion in the precipitate, and lower recoveries ensue.

Biological samples are also purified by ultrafiltration techniques. The technique is used for rapid removal of low-molecular-weight (<50 000 molecular mass) dissolved solutes from the biological matrix by passing through an anisotropic membrane filter under centrifugal force. This technique is widely used to concentrate proteins and is applicable to small sample volumes.

Dialysis can separate an analyte from the matrix by diffusion through a semipermeable membrane that retains macromolecules, and allows passage of solute molecules of molecular weight below 5000. Diffusion is a slow process and is driven by a concentration gradient until equilibrium is established. It can only be applied to compounds that are relatively weakly protein bound. The use of dialysis for sample preparation is normally not recommended as it is time-consuming and the sample becomes diluted.

Hydrolysis is also used in the preparation of samples for analysis. It is applied where analytes are present in their conjugated form in biological samples. This is accomplished by the use of either enzymes such as ß-glucuronidase and arylsulfatase, or nonspecific strong acids or bases. The aim of the technique is to cleave the conjugate and release the original compound for assay.

Liquid–liquid extraction (LLE) is a versatile technique that is commonly used for sample preparation. In LLE, the pH of the aqueous phase is adjusted so that the analyte to be extracted is virtually undissociated, thus facilitating extraction into the solvent. An advantage of LLE is its selectivity. Depending on the choice of the solvent and pH adjustment of the aqueous phase, the compound of interest can be isolated. The success of an extraction step depends on knowledge of the polarity of the analyte. Additional selectivity can be imparted to an extraction method by multiple extraction procedures or back extraction whenever required. One of the problems frequently encountered in LLEs is the formation of emulsions that causes loss of analyte by occlusion within the emulsion, leading to lower recoveries. Emulsion formation can be minimized by the use of a large volume of the extracting solvent, by less rigorous mixing, centrifugation, and ultrasonication, stirring with a glass rod, or filtration through a loose bed of glass wool or phase-separation filter paper. An increase in ionic strength by addition of salt (sodium chloride, potassium bromide) or a small amount of ethanol or ethyl-1-hexanol may cause a decrease in the forces stabilizing the emulsion. Other drawbacks of the procedure are lack of speed, the need for large solvent volume, and possible low analyte recovery.

The use of the commercial liquid–liquid disposable columns (Chem Elut™, Tox Elut™, Extrelut™, etc.) has gained popularity for isolation of compounds from biological specimens. These columns contain diatomaceous earth as an adsorbent. Some of the limitations of conventional LLE are overcome by the use of these columns.

Solid-phase extraction (SPE) currently is a major sample preparation tool. The isolation of the compound by this method depends upon the relative affinity of the analyte in a biological matrix for the solid adsorbent and the relative ease of eluting the compound for subsequent analysis. The conventional sorbents such as carbon, celite, alumina, nonionic resins, ionic exchangers, and Sephadex™ gel are still widely used for sample preparation, but the recent trend has been to use chemically modified silicas. Many different types of SPE cartridges are commercially available. The main advantage of SPE is its selectivity due to its wide choice of sorbents available. By proper selection of disposable SPE cartridges/minicolumns and the eluting solvents, analytes with a wide range of physicochemical properties can be isolated from biological samples to facilitate chromatographic separation. Other advantages include low solvent consumption, short throughput times, clean extraction, high recovery, elimination of emulsions, and reproducible results. The techniques provide an attractive alternative to traditional sample preparation methods.

At the present time, use of a preadsorbent-zone plate greatly facilitates the sample cleanup procedure. The preadsorbent zone[2,6–7] retains interfering solutes on the preadsorbent zone in the lower part of the plate and causes analyte preconcentration, leading to increased selectivity and sensitivity. The latest development in bioanalysis is the introduction of particle-loaded membranes.[22] Particle-loaded membranes are available in disks with diameter of 4–90 mm. Normally 4-mm disks are used in drug tubes for the analysis. The main advantage of using drug tubes is the small desorption volume and, therefore, increased sensitivity. Moreover, in many cases particle-loaded membranes are more efficient than packed solid-phase cartridges.

2.3 Sample Application

Sample application is a crucial step in all TLC separations. The size and shape of spot are important for

obtaining good chromatographic resolution. For qualitative purposes, the samples are usually spotted by means of a micropipette or microsyringe or disposable glass capillaries, whereas automated application devices are used for quantitative TLC. Generally 5–15 μL of extracts are applied in the form of spots or narrow bands to the plate. The amount of the sample to be spotted will depend on the thickness of the plate and also on the composition of the sample. For accurate spotting, templates are used. Evaporation of the sample solvent is aided and application is made faster if a stream of cool air or inert gas is blown gently across the plate being spotted.

2.4 Equilibration

It is essential to prepare the developing chamber before the TLC separation. This is done by filling the developing tank with the mobile phase to a depth of 0.5–1.0 cm and lining three sides of it with filter paper. The tank is allowed to stand for at least 1 h with a lid over the top to ensure that the atmosphere within the chamber becomes saturated with solvent vapor (equilibration). Saturated chambers give faster separation, a straight solvent front, and reproducible and consistent R_f values.

2.5 Development

After spotting, the TLC plates are developed in the equilibrated developed chamber. The mobile phase rises with the help of capillary force. When the developing distance is reached, the plate is removed from the tank and the solvent front is marked for calculation of R_f values. The plate is then dried at room temperature or in an electric oven. In recent years, various development strategies have been devised that improved the performance and speed of the TLC separation.[23,24] The methods include programmed multiple development (PMD), automated multiple development (AMD), continuous multiple development, circular or radial and anticircular development, overpressured TLC, two-dimensional TLC, two phases two-dimensional TLC, triangular development, and centrifugal development.

2.6 Qualitative and Quantitative Evaluation

In conventional TLC, detection is a static off-line procedure. Colored or fluorescent spots are easily detected under white or ultraviolet (UV) light. Some analytes exhibit native fluorescence characteristics upon UV irradiation (e.g. porphyrins) and are detected at very low concentrations. To improve the sensitivity and selectivity of detection, derivatization techniques are sometimes used in TLC. Some spots can be made visible, absorbing, or fluorescent with various chemical reagents before (prechromatographic) or after (postchromatographic) the separation process. Postchromatographic derivatization reagents can be applied by means of spraying or dipping. Automated spraying devices and the dipping technique facilitate the even distribution of reagent over the layer, compared to manual spraying. This method has the advantages that by-products of the derivatization reagents do not interfere in the chromatography and all samples are derivatized simultaneously.

Qualitative analysis is done by comparing R_f values, or relative R_f values, of the unknowns with those of standards that have been developed under identical experimental conditions on the same layer.

Two approaches are used for quantitation of samples in TLC:

1. Indirect methods: in these methods, quantitative measurements are carried out by visual comparison of colored or chemically visualized zones or excizing of separated zones from the layer followed by elution from the sorbent and spectrophotometric analysis. These methods are insensitive, labor intensive, and tedious.
2. Direct methods: in these methods, the separated spots are evaluated in situ on the plate. The recorded detector signal can be plotted against the amounts of the reference sample providing a calibration curve that is useful for quantitation over the desired range.

Scanning densitometry is the most efficient procedure for quantitative evaluation.[1–9,25] In situ, quantitative measurements of TLC plates can be performed in many ways. The reflectance, transmittance, simultaneous reflectance and transmittance, fluorescence, or fluorescence quenching of a spot can be measured by use of a densitometer. The most sensitive in situ method is fluorimetry. The methods are based on measuring the difference in optical response between blank portions of the medium and regions where a separated substance is present. Significant advances in technology have been made in the densitometric technique. Modern densitometers have a high degree of automation, both in the recording process and in manipulation of the data obtained. Scans can be repeated for all or part of the chromatogram, without the need to rerun samples. This characteristic of TLC permits the use of additional detection techniques between scans that can aid in the identification of the unknown material.

Furthermore, current developments in detection methods for TLC also include in situ methods of detection without mechanical scanning using image analyzers, the use of laser sources to enhance sensitivity, and coupling devices such as TLC/MS and TLC/FTIR to provide structural information as well as quantification.[1–9,25]

2.7 Validation of Results

Validation of results is prerequisite in the analysis of biological samples, as the analytical result aids in making a diagnosis and in treatment of diseases in patients. The validation of PC methods requires the demonstration of calibration linearity, reproducibility, specificity, sensitivity, extraction recovery, precision, and accuracy.

Calibration is one of the important steps in quantitative chemical analysis. Without a good calibration procedure, precision and accuracy cannot be obtained. In general, calibration standards of the test compound in a particular biological fluid are prepared by adding pure reference test standards to blank biological samples. A fixed amount of internal standard in each sample can also be added to evaluate good and consistent recovery. The blank samples are included in the calibration samples to ensure that no interferents that are coeluted with the analyte or the internal standard are present in the sample or introduced during sample preparation. Control spiked samples, blank samples, and the unknown samples are then processed in an identical condition. The processed samples are spotted on the TLC plates, developed, and scanned with the densitometer, with or without spraying of detection reagent. Other details of quantitation and calibration linearity have been discussed elsewhere.[11]

In order to check the reproducibility of the results, chromatography can be repeated three or four times on different plates and the mean value of experimentally obtained data can be plotted for each concentration spotted. Sometimes the same volume of each processed sample can be spotted in triplicate on the plate, the mean being used for calculation. Moreover, each spot can be scanned in triplicate to establish the instrumental error.

Specificity of a test is defined as its ability to distinguish between closely related compounds and their metabolites. Specificity of a chromatography assays largely depends on sample processing as well as on the chromatographic separation.[11] Lack of specificity can lead to false positive results, and, therefore, a high degree of specificity is generally desirable.

Sensitivity is defined as the minimal concentration of an analyte in the original undiluted biological fluid that is detectable with a high probability. The sensitivity of an assay is often dependent on the conditions of analysis, purity of reagent, sample matrices, and instrument system. As mentioned earlier, considerable progress has been achieved in stationary phases, chromogenic spray reagents, instrumentation, and automation of the various steps involved in planar chromatographic procedures. Because of these developments of TLC methods, sensitivity has been considerably enhanced and it is similar or identical to that of other chromatographic methods such as HPLC.

Precision is a measure of variability of the results. The precision of the analysis is estimated as the standard deviation or relative standard deviations (coefficient of variation) of a set of replicate results. The precision may relate to the within-laboratory error of a method (repeatability) or to the between-laboratory error of a method (reproducibility).

Accuracy is a measure of systematic deviation of the results obtained from the true values. The accuracy is estimated as the percentage differences (bias) between the mean values and the true or known concentrations. The accuracy of a method is usually expressed in terms of percentages of recovery. In the authors' view, assay results with $\leq$10% relative standard deviation and $\leq$10% bias may be considered acceptable. Analysts should always attempt to improve the precision and accuracy of their assays.

The recovery of an analyte from the biological matrix is also an important step in all chromatographic methods. Recovery of compounds greatly affects the sensitivity, precision, and accuracy of the test procedure, and recovery should also be reproducible. Recovery may be concentration-dependent. The exact recovery can be estimated by comparing the slope of the calibration curve based on the calibration standards prepared by spiking with accurately measured amounts of test compounds of high purity (reference standard) and processed as per the assay procedure with the slope of the calibration curve of the pure unprocessed reference test compound of the same concentration. Recovery of an analyte in a particular assay procedure can be monitored by the use of an internal standard. As defined, the recovery should be close to 100% to determine the reliability of TLC. Replicate experiments (at least two or more replicates) should be carried out on different representative samples. Use of various analytical techniques (e.g. HPLC, gas–liquid chromatography (GLC), GC (gas chromatography)/MS) is also helpful in validating the results of TLC.

3 RECENT DEVELOPMENTS IN THIN-LAYER CHROMATOGRAPHY PLATES

Traditionally, TLC has been performed using inorganic and organic sorbents such as alumina (neutral and acidic), magnesium silicate, diatomaceous earth (kieselguhr), cellulose, polyamide, ion-exchange resins (Dowex™50-X8), Sephadex™, and so on, coated onto glass, plastic, or aluminum foil. Silica gel continues to be one of the most widely used layer materials for PC. However, during the 1990s considerable progress took place in the preparation of bonded-phase silica layers. A range of

alkyl-bonded silica TLC plates are now commercially available. These include C_{18}, C_{12}, C_8, C_2, aminopropyl, diphenyl, and cyanopropyl bonded plates, as well as plates coated with a chiral complexing agent for the separation of amino acid enantiomers and similar compounds. Furthermore, precoated plates with concentrating zones are also available. The introduction of bonded silica has led to a renewed interest in reversed-phase TLC (RPTLC). RPTLC has proved quite useful for the chromatography of polar compounds. Advantages of RPTLC over normal-phase TLC (NPTLC) are higher recoveries of materials from the plate, ease of optimization of solvent systems, and minimum decomposition of sensitive compounds.

Another major development in TLC has been the introduction of HPTLC plates. Modern HPTLC plates differs from conventional TLC plates in number of ways. These plates are smaller in size (10×10 or 10×20 cm), precoated with smaller size particles (2–7 μm), have narrow particle size distribution, and have smooth surface and thinner layers (0.2 mm). Other characteristics of HPTLC compared with TLC include smaller sample volume, economy, faster separation, reduced diffusion leading to improved separation efficiency, more reproducible results, and lower detection limits (by a factor of 10–15). Thus, separation and quantification can provide results that are comparable with other analytical methods such as HPLC.[11,25]

4 COMPARISON OF INSTRUMENTAL THIN-LAYER CHROMATOGRAPHY WITH OTHER ANALYTICAL TECHNIQUES

Quantitative thin-layer chromatography (QTLC) has gained the analyst's interest. It has been established that HPLC and QTLC have their specific merits and often complement one another. Typical features of QTLC are:[11,26]

1. Simple sample preparation because the stationary phase is disposable and, therefore, contamination of the stationary phase by the sample matrix can be accepted. Conversely, sample preparation for HPLC is critical, since the stationary phase is expensive and intended for multiple reuse.
2. Large sample volumes can be applied using a special spray-on technique. This often eliminates a preconcentration step.
3. The off-line character has many advantages but does not lead to expense.
4. Sample throughput is higher than in any other chromatographic technique. A large number of samples can be chromatographed simultaneously, making TLC even quicker than fully automated HPLC.
5. Any solvent may be used for QTLC irrespective of its UV cut off as the mobile phase (solvent) is evaporated prior to detection (quantitative measurement).
6. Mobile phase use is much less than that required for HPLC, hence QTLC is economical.
7. All substances (fractions) are permanently stored on the plates and are unaffected even after scanning. This makes it possible to repeat detection (scanning) of one, several, or all fractions of the chromatogram with the same or with different parameters. Moreover, the same plate can be used for recording the absorbance of the positively identified fractions and to recover the fractions for further analysis.
8. Two-dimensional chromatography is not possible in HPLC.
9. Any combination of mobile and stationary phases cannot be used in HPLC for the fear of irreversibility damaging the expensive column.
10. Positive identification of fractions is not a problem. Identification can be achieved by cochromatography of standards, in situ spectra recording, identification reactions, and combinations of these.
11. Running costs (solvents) and costs per sample analysis are relatively low in comparison to HPLC.

HPLC has certain distinct advantages over QTLC.

1. The chromatographic resolution power of HPLC is better than that of QTLC owing to the short migration distance of the latter.
2. The quantitative precision of HPLC is somewhat better than that of QTLC.

5 APPLICATIONS OF PLANAR CHROMATOGRAPHY IN CLINICAL CHEMISTRY

PC is widely used in clinical laboratories for detection of a number of substances such as amino acids, bile acids, cerebrosides, drugs and their metabolites, gangliosides, lipids, phospholipids, porphyrins, prostaglandins (PGs), and so on. Owing to the limitations of the article length, it is not possible to cover all of the applications in detail. With these objectives and caveats in view, important selected applications of the technique are discussed below.

5.1 Amino Acids

The use of PC for separation of amino acids is very well documented in the medical sciences. In clinical laboratories, the estimation of free acids in biological fluids and tissues by TLC aids in making a diagnosis of inborn errors of amino acid metabolism,[27–31] classic cystinuria,[32] heterozygous cystinuria,[33] aminoacidopathies,[34] Alports' syndrome,[35] and so on. Prior to TLC analysis of amino acids, purification of the specimen is essential. Cellulose, silica gel, ion exchange, and alkyl-bonded stationary phases are mainly used for separation of amino acids.[2,11] Some researchers[36,37] have developed a method in which amino acid patients with leucinosis, citrullinuria, and phenylketonuria do not require deionized urine or deproteinized serum samples for amino acid analysis.

Amino acid separation[6,7] have been studied in several PC systems: 24 acids on papers impregnated with Sn(IV) and Th(IV) phosphosilicate cation exchangers using water, alcohols, acids, acetone, benzene, ether, and phenol as developing solvents; 15 acids with *n*-butanol–acetic acid and combined with water, chloroform, or ethyl acetate as mobile phases on plain and nickel chloride-impregnated silica gel plates; chitin layers with monocomponent and binary mobile phases; 14 acids on mixed adsorbents containing silica gel and alumina or cellulose with benzene-containing mobile phases; α-amino acids on antimony(V) phosphate silica gel plates in different aqueous, nonaqueous, and mixed-solvent systems; racemic dinitropyridyl, dinitrophenyl, and dinitrobenzoyl amino acids on RPTLC plates developed with aqueous–organic mobile phases containing bovine serum albumin and chiral agent; 4-(*N*-*N*-dibutylamino)azobenzene-4-thiohydantoin derivatives of 15 α-amino acids on antimony(V) phosphate silica gel plates in different aqueous, nonaqueous and mixed-solvent systems; phenyl thiohydantoin(PTH) derivatives of the 20 common protein amino acids by AMD on silica gel plates. Three new solvent systems, pyridine–benzene (2.5 : 20), methanol–carbon tetrachloride (1 : 20), and acetone–dichloromethane (10.3 : 8.0) for the resolution of mixtures of 18 PTH amino acids have been reported and have proved very successful.[36] Direct resolution of enantiomers of amino acids by impregnated TLC has also gained popularity in biomedicine.[37,38]

In general, ninhydrin is used as a staining reagent for qualitative and quantitative detection of amino acids. A modified ninhydrin reagent prepared by addition of D-camphor and various acids for improved identification of amino acids has been reported.[39,40] Sensitivity limits and color differentiation in amino acid detection were further enhanced by spraying layers with 1,3-indanedione or *o*-thiobenzoic acid prior to ninhydrin.[41]

5.2 Bile Acids

Bile acids are 24-carbon steroid derivatives. For clinical purposes, measurement of bile acids in biological specimens (bile, serum, duodenal contents, and crude faecal extracts) aids in making diagnosis of certain liver or intestinal disorders.[42,43] Many methods are used to quantitate either total or individual bile acids in biological samples. These include spectrophotometry, immunoassays, chromatographic techniques, GC/MS, capillary electrophoresis, and so on. Each technique has its own advantages and disadvantages. In clinical practice, TLC is still accepted for the separation of bile acids. Scalia published a review of the chromatographic methods and combined detection system that can be applied to the analysis of bile acids.[44]

Sample pretreatment is essential before the sample is subjected to TLC analysis. Kindel et al.[45] describe an easy, precise, and rapid TLC method for simultaneous determination of five predominant bile acids (cholic, chenodeoxy cholic acid, deoxycholic acid, litocholic acid, and ursodeoxycholic acid) in human stool specimens on a silica gel plate using two different solvent systems. The plates were chromatographed with isooctane–2-propanol–acetic acid (30 : 10 : 1) for 40 min, dried, and chromatographed again with isooctane–ethyl acetate–acetic acid (10 : 10 : 2) for 65 min. Quantification of bile acids was achieved by dipping the plate vertically (for 2 s) into a 0.2% 2,7-dichlorofluorescein ethanolic solution and fluorescence was measured by direct scanning.

Ferreira et al.[46] proposed a binary mixture (methanol–chloroform, 2.5 : 97.5) for separation of pentachlorophenyl esters of bile acids. Ida et al.[47] presented a TLC method for the separation of methyl esters and hydroxylated derivatives of methyl-5-β-cholanate.

The use of alkyl-bonded phases, such as cyano-bonded silica, is increasing for the separation of bile acids.[2] RPTLC plates are also effective for separation of di- and trihydroxy stereoisomers, whereas the less polar monosubstituted isomers are well resolved in a normal phase system. Sometimes combinations of both systems are very efficient.

Fluorimetry is the most sensitive detection technique used for detection and quantification of free and conjugated bile acids.[48] Bile acids are converted into fluorescent derivatives by reaction with 5% perchloric acids in methanol.[49] Spraying with 10% sulfuric acid and subsequent heating yields fluorescent, light blue spots on a dark violet background.[2]

Recently, Tonelli et al.[50] have studied bile acids kinetics in humans by radio TLC and densitometry coupling. Thus, TLC has proved successful for characterizing bile acid metabolism inside the enterohepatic circulation.

5.3 Carbohydrates

Several diseases are accompanied by increased elimination of various sugars in biological samples. Detection and identification of these sugars constitute an important step in establishing diagnosis of certain diseases. Chromatographic separation of sugars is well documented.[2,6,7,11] Paper chromatography and TLC techniques are quite effective for separation of sugars, but now the use of paper chromatography is declining in clinical laboratories mainly owing to long development times.[51]

In biomedicine, the determination of various monosaccharides and disaccharides in biological samples (urine, plasma) by TLC has been established to evaluate the extent of malabsorption and intestinal permeability disruption in several infections and nutritional diseases, including human immunodeficiency virus (HIV) infection.[52–56]

TLC has also proved quite successful for separation of urinary oligosaccharides in diagnosis of inherited lysosomal storage disorders.[57–60] The improved selectivity of urinary oligosaccharide screening using a one-dimensional TLC system has been examined by Abeling et al.[61] Higashi et al.[62] have also reported the quantitation of oligosaccharides by the TLC densitometric technique. Vajda and Pick[63] have developed an improved method for separation of mono-, di-, and trisaccharides on a silica gel HPTLC plate with acetonitrile–aqueous ammonia–aqueous potassium chloride, mobile phase, followed by ethanolic orcinol–sulfuric acid detection. The adsorbents that are used for TLC separation of sugars are magnesium silicate, alumina, kieselguhr, silica gel or a mixture of kieselguhr and silica gel, and aminopropyl-bonded silica.[11] Bhushan and Kaur[64] have reported the separation of some common sugars on silica gel plates impregnated with transition-metal ions in two different solvent systems and using $KMnO_4$ (0.5%) in 0.1 M NaOH as the detection reagent. Separation of sugars[2,11] in biological samples has been recommended on silica gel with binary, ternary, or quaternary mixtures of solvents such as butanol (water-saturated)–triethylamine, ethyl acetate–methanol–acetic acid–water, propanol–methanol–water, propanol–water, ethylacetate–isopropanol–water, isopropanol–*n*-butanol–acetone–aqueous boric acid, acetonitrile–phosphate buffer, acetonitrile–*n*-butanol–ethyl acetate, acetone–aqueous ammonia, and so on. Use of postchromatographic derivatization reagents such as aniline, diphenylamine, phosphoric acid, 4-amino hippuric acid, aniline–phosphoric acid, 2-aminophenol, anthrone, vanillin, and zinc chloride, and so on have also enhanced the detection limit of sugars in nanogram range.[2]

5.4 Drugs

The importance of the analysis of drugs in biological samples in medicine, toxicology, pharmacology, forensic medicine, de-addiction programs, and other biomedical disciplines is well documented.[11] Drug analysis can be carried out in various biological samples, viz. blood, urine, saliva, gastric contents, tissues, and so on. The type and quantity of sample to be tested depend upon the program needs. For instance, urine is used for screening drugs of abuse, because acquisition of sample is noninvasive and most abused drugs can be detected in urine for a reasonable duration after ingestion.[65,66]

Various immunoassays, chromatographic methods, and MS techniques are used for drug analysis in clinical laboratories.[67] The optimal choice to be adopted depends on cost, work load, program needs, and how the data is used for the chromatographic technique. Of the chromatographic techniques, silica gel TLC is widely used for multiple drug screening programs.[68] All samples to be used need prepurification before they are submitted to chromatographic analysis. Further details of sample preparation have been discussed earlier.

Siek et al.[69] have developed a computer-aided identification of thin-layer chromatographic patterns in broad-spectrum drug screening. The computer program assists in matching the data from a particular chromatogram with those obtained for known drugs or their metabolites recovered from serum, urine, or other specimens. The plates were developed in a single mobile phase. Visualization and detection reagents used to characterize unknowns include fluorescamine, ferric chloride/perchloric acid/nitric acid, dragendorff, marquis, mandelic, and iodinated dragendorff solutions, 254-nm UV light, and vapor from chlorine or hydrochloric acid. This method proved to be very sensitive as detection limits of 5–200 ng per sample spot were obtained for drugs in the database.

For toxicological and for drug-abuse screening programs, silica gel TLC remains the most commonly used PC method.[14,15,66,70,71] Recommended solvent systems[70] used for separating these abusable drugs are: ethyl acetate–methanol–ammonium hydroxide (85 : 10 : 5) for opioids and basic drugs, chloroform–acetone (90 : 10) for barbiturates and other acidic drugs, and heptane–diethyl ether–acetic acid (80 : 10 : 4) and chloroform–methanol–ammonium hydroxide (85 : 15 : 2) for cannabinoids. Chromogenic sprays used for detecting abusable drugs include ninhydrin (amphetamine and primary amines), diphenylcarbazone and mercuric sulfate (barbiturate and gluthemide), iodoplatinate (narcotic analgesics and cocaine, phenothiazine, antidepressants, antihistamine), dragendorff's reagent (narcotic analgesics), and fast blue BB salt and fast blue B salt

(cannabinoids). Currently, commercial TLC systems such as Toxi-Lab™[71,72] are used for screening abusable drugs and toxic substances. However, results indicate that in-house horizontal TLC methods are better and more efficient compared to commercial TLC (Toxi-Lab™) for screening urinary opioids.[73] In contact, the Toxi-Lab™ technique was found to be more effective in detection of amphetamine in comparison to TLC.[74]

Ojanpera et al.[75] have reported combination of NPTLC and RPTLC plates for screening 25 amphetamine-type drugs. These authors used fast black K salt for visualization and the mean list length method for evaluation. Identification and quantification of abused drug, viz. cannabinoids,[76] buprenorphine,[77] benzodiazepine,[78,79] and heroin,[80] by densitometric techniques on HPTLC and TLC plates have also been reported.

Currently, many papers have been published using quantitative densitometric HPTLC methods and coupled spectral methods for pharmacokinetic and metabolic studies of drugs in biological fluids[81–85] and for therapeutic monitoring of drug levels to ensure drug dosage.[86–89] These methods proved to be sensitive, economical, and successful.

5.5 Lipids

Lipids play an important role in cell structure and function. They may be polar (phospholipids or sphingolipids), nonpolar, or slightly polar (cholesteryl esters, triglycerides, cholesterol, etc.). Lipid measurement is of greatest interest in blood, serum, faeces, tissues, and amniotic fluids. Lipid profiles are known to change with disease and their analysis holds considerable potential for clinical diagnosis. The investigation of serum lipids, mainly cholesterol ester, has great diagnostic value for hepatic diseases and lipid metabolism disorders. In lipid storage disease, accumulation of cholesterol occurs in blood and tissues. Hyperlipidemia indicates high risk factors of cardiovascular diseases. Serum lipid analysis is important in skin disorders.[90]

The chromatography of lipids and particularly the PC of lipids is well documented in biomedicine. It provides rapid and complete separation of most neutral and phospholipid classes. Numerous reviews and texts dealing with chromatographic analysis of lipids have appeared.[2,11,91–93] Owing to space limitation, these cannot be discussed at length in this article.

Lipids are primarily extracted from biological samples before they are subjected to chromatography. Preliminary extraction is mainly performed by the classical extraction procedure of Folch et al.[94] with chloroform–methanol (2 : 1). There are numerous modifications of this method. Another useful method is the SPE extraction procedure for purification of lipids.[95,96] In sterol storage disease, accumulation of cholesterol occurs in blood and tissue. The use of TLC for cholesterol determination after extraction of serum with hexane has been reported.[93] The extract was subjected to peracetic acid followed by hydrogen sulfide oxidation. Separation of cholesterol was achieved in silica gel 60 HPTLC with heptane–ethyl acetate (60 : 40) and visualization by spraying with phosphomolybdic acid (PMA) reagent. Batta et al.[97] separated cholest-5-enzone and epicholesterol on silica gel plates using mobile phases containing different proportions of acetone in methylene chloride, chloroform, or carbon tetrachloride. Spots were detected by spraying the plates with PMA (3.5% in isopropanol) followed by sulfuric acid (20%) and heating at 110 °C for 2 min. Clinical biochemical and histological analyses of patients with cholesteryl ester storage disease and Wolfman's disease have been reported.[98] The overpressured and conventional TLC methods were utilized by Pucsok et al.[99] for separation of cholesteryl esters. Bhat and Ansari[100] reported an improved method for separation of chloro analogues of cholesterol and its acetate in tissue samples on silica gel TLC plates using mixtures of hexane–ethyl acetate as mobile phases. The plates were sprayed with 50% sulfuric acid followed by heating at 120 °C for 5 min to detect cholesteryl acetate.

The stratum corneum lipids are unique in composition and have been used frequently as a model of the skin's lipid barrier. Serizawa et al.[101] separated cholesterol sulfate from intercellular stratum corneum in studies related to horny layer adhesion. Extracted lipids were spotted on HPTLC plates, and developed in multiple mobile phases. Spots were detected by spraying with 10% cupric sulfate in 8% phosphoric acid followed by heating at 80 °C for 60 min. Edouard et al.[102] reported separation and quantification of free cholesterol and cholesteryl esters in skin biopsies by TLC and suggested this technique can be used as a diagnostic tool to detect pathologies of skin lipid metabolism. Zellmer and Lasch[103] used HPTLC/AMD with a 25-step gradient based on methanol, diethyl ether, and *n*-hexane to separate six major human plantar stratum corneum lipids. Postchromatographic staining of these lipids with a solution of $MnCl_2-H_2SO_4$ at 130 °C or a solution of $CuSO_4-H_3PO_4$ at 140 °C allowed visualization and quantification of the lipids.

Asmis et al.[104] have published a low-cost TLC procedure for the quantification of cholesterol, cholesteryl esters, and triglycerides in small biological samples using TLC and laser densitometry. Alteration of acidic lipids in human sera during the course of pregnancy also suggests a characteristic increase in the concentration of cholesterol sulfate.[105]

TLC is also used for separation of lipids from patients with alcoholic diseases such as alcoholic fatty liver which

is accompanied by a major increase in triglycerides and a smaller increase in cholesteryl esters.[106]

Analyses of the lipids of normal and Gaucher bone marrow using TLC and HPLC methods have also been reported.[107] Yamada et al.[108] have published a quantitative analysis of lipids from Schnyder's corneal dystrophy using the TLC/FID (flame ionization detection) technique. Findings suggest that this disorder involves a disturbance of the metabolism of cholesterol and/or sphingomyelin metabolism in the cornea. Ohta et al.[109] have developed a rapid and quantitative procedure for determination of the fatty acid composition of plasma lipid using silica gel plates with partial development in methanol followed by chloroform–methanol (1:1) and full development in hexane–diethyl ether–acetic acid (80:20:1). This method has proved quite useful for screening a large number of plasma samples. Kaphalia and Ansari[110] reported a simple and reliable single-step TLC method for quantitation of enzymatic formation of fatty acid anilides.

5.6 Phospholipids

Phospholipids are polar lipids and include phosphoglycerides and sphingolipids. These are amphipathic constituents of membrane. They play an essential role in the synthesis of plasma lipoprotein. The determination of phospholipids is important in biomedicine. Surface active phospholipids have an important influence on the mechanical behavior of the lungs. Clinical management of high-risk pregnancies often requires determination of fetal lung maturity status.[111–113] Measuring phospholipids in amniotic fluid as the lecithin/sphingomyelin ratio using the silica gel TLC method has been the established clinical procedure for predicting fetal lung maturity.[111–113] Radial HPTLC has also been employed to analyze phospholipids in more than 2000 specimens of amniotic fluid to assess fetal lung maturity.[114] Iwamori et al.[115] have reported a sensitive TLC-immunostaining procedure for the diagnosis of respiratory distress syndrome. A large number of papers have appeared.[115–118] Prior to chromatography, purification of phospholipids is essential. The extraction of lipids is often carried out by the method of Gluck and Kulovich (described in Siouffi et al.[2] and Jain[11]) or by the modified procedure of Kollins et al.[118] A SPE extraction procedure using C_{18} extraction cartridges has also been reported.[119,120] Both one- and two-dimensional TLC procedures have been reported for the estimation of phospholipids.[2] The common mobile phases used are mainly mixtures of chloroform–methanol–water, chloroform–methanol–ammonium hydroxide, and chloroform–methanol–glacial acetic acid–water.[121] Improved resolution of lecithin and sphingomyelin occurs with addition of either acid or base to the water. The use of HPTLC plates for analysis of phospholipids in amniotic fluid has also been reported.[93] Amniotic fluids were extracted with chloroform–methanol solution. Extracts were spotted on HPTLC plates predeveloped in chloroform–methanol (1:1). The plate was first developed in chloroform–ethanol–triethylamine–water (30:34:30:8) for separation of polar lipids, including sphingomyelin, phosphatidylcholine, lysophatidylcholine, phosphotidylserine, and phosphatidylinositol. After drying the plate was redeveloped in hexane–diethyl ether (50:50) to separate the cholesteryl ester fraction and resolve phosphatidylglycerol and cardiolipid . Detection was achieved by dipping the plates for 5 s in a 10% solution of $CuSO_4$ in 8% H_3PO_4 followed by heating at 120 °C. Quantitation was carried out with a spectrodensitometer at 310 nm.

The determination of phospholipids is also important in patients suffering from cystic fibrosis.[122] Plasma phospholipids were separated on HPTLC silica gel fluorescent plates impregnated with 0.75% boric acid in absolute ethanol with hexane–diethyl ether (6:4) mobile phase and the phospholipid fatty acid pattern was determined by GLC. Li et al.[123] have studied the detection of serum antibodies against phosphocoline containing aminoglycoglycerolipid specific to *Mycoplasma fermentans* in HIV (HIV-1) infected individuals using TLC.

Leray et al.[124] reported a rapid quantitative analysis of vitamin E, cholesterol, and phospholipid fatty acids in a single aliquot of human platelets and cultured endothelial cells. The whole procedure is based on the extraction of total lipids followed by TLC and microcolumn purification of tocopherols and cholesterols. The fatty acid compositions of phospholipid classes were separated on the same silica gel plates and determined by GLC.

Ceramides and 1,2-diacyl glycerol have been demonstrated in intracellular signalling pathways. Okumura et al.[125] developed a rapid method of simultaneous quantitative determination of ceramides and 1,2-diacylglycerol in tissues by the TLC/FID technique.

A sensitive TLC–densitometry method has been reported for the determination of the platelet activating factor (PAF) and phospholipids in human saliva and tears.[126,127] The mobile phase used for separation of lipids and phospholipids was hexane–diethylether–water (65:35:7). Detection was achieved by spraying the silica gel plates with phospholipase C followed by alkaline phosphatase solution at 45 °C to liberate phosphate from each phospholipid. The plate was resprayed with a mixture of ammonium molybdate and malachite green. The liberated phosphates appeared as blue-green spots of molybdophosphate–malachite green aggregation on a yellow-brown background. The absorbance of each spot

on the plate was measured at 620 nm with a densitometer for quantitative analysis.

TLC and laser densitometry have also been used to examine erythrocyte membrane phospholipids in psychotic patients.[128] Alteration of serum phosholipids is also seen in patients with multiple sclerosis.[129] TLC–densitometry was used for separation and quantification of these phospholipids. Analysis of phospholipid and their fatty acid composition from human intestinal mucosa was performed with two-dimensional TLC followed by lipid-phosphorus determination.[130]

There is an increasing interest in the role of antiphospholipid antibodies, and detection of these antibodies by immunostaining has proved very successful.[131] Khan and Glenton[132] have shown that patients with calcified kidney stones excrete more lipids and acidic phospholipids than normal individuals. These authors separated neutral lipids with hexane–ether–glacial acetic acid (70 : 30 : 1), glycolipids with chloroform–methanol–water (100 : 42 : 6) and phospholipids with chloroform–methanol–glacial acetic acid–water (75 : 45 : 3 : 1) on silica gel plates. Individual lipid spots were revealed by exposing the plate to iodine vapor and phospholipids spots were located by staining with molybdenum blue. Existence of a lipid gradient in the upper stratum corneum has also been established by Bonte et al.[133]

Numerous papers have also appeared on blotting of lipids, glycolipids, phospholipids, and gangliosides from an HPTLC chromatogram to a polyvinyldiene difluoride membrane.[134–137] TLC in combination with HPLC has been used for the assay of fatty acids composition of individual phospholipids in platelets from noninsulin-dependent diabetes mellitus patients.[138] Phospholipids of many cancer tumors also contain larger amounts of alkyl ether than healthy tissues. Narayan and Dahiya.[139] studied alterations in sphingomyelin and fatty acids in human prostatic hyperplasia and prostatic cancer by using TLC and GLC techniques. A number of reports have been published for separation and quantification of neutral lipids and phospholipids using TLC coupled with other techniques, and these methods have proved quite successful.[140–145]

5.7 Porphyrins

Porphyrins are tetrapyrrole derivatives with a porphine structure. They are chemical intermediates in the synthetics of hemoglobin, myoglobin, and other respiratory pigments called cytochromes. Detection and identification of porphyrins and their precursors in biological samples are of paramount therapeutic importance.[146–158] They are analyzed in clinical chemistry to aid in the diagnosis of a group of disorders called porphyrias, which result from disturbances in the heme biosynthesis. The accumulation and overproduction of these intermediate compounds in tissues, blood, urine, and feces indicate a metabolic block in heme synthesis. These disorders are associated with acute or cutaneous manifestations (or both).

Analysis of porphyrins in urine or feces involves lipid precipitation from acetone and subsequent extraction with chloroform before they are subjected to chromatography. Increasing numbers of papers advocate the use of HPLC and MS techniques for analysis of urinary and fecal porphyrin excretion patterns in humans.[146–152] Urinary and fecal porphyrin patterns are characteristic of each type of porphyrin. TLC is still widely used for the routine examination of porphyrins in clinical laboratories. Separation of porphyrins by TLC with prior derivatization offers a sensitive, rapid, and reliable method of clinical diagnosis.[151] The developing solvent systems that are commonly used for separation of porphyrins are binary mixture of hexane with methylene chloride, chloroform, or ethyl acetate, and ternary mixtures of benzene–ethyl acetate–methanol, toluene–ethyl acetate–methanol, methylene chloride–carbon tetrachloride–ethyl acetate, chloroform–kerosene–methanol or quaternary mixtures of methylene chloride–carbon tetrachloride–ethyl acetate–ethyl propionate. Free carboxylic porphyrins can be separated with the ion-pairing technique or an alkyl-bonded layer with a mobile phase consisting of acetonitrile-*N*-cetyl-*N*,*N*-trimethyl ammonium bromide, 0.1 mM in aqueous acetate buffer.[153]

Huie and Williams[154] reported an application of HPTLC with laser fluorimetric detection of porphyrin methyl esters in human urine. This method demonstrated good selectivity and detectablity for determination of porphyrin profiles. The detection limits for uro-, heptacarboxy-, hexacarboxy-, pentacarboxy-, copro-, and mesoporphyrin methyl esters were in the 18–35 pg range.

Jacob and Das[155] published the excretion pattern of fecal coproporphyrin isomers (I–IV) in human porphyrias. These authors developed a reliable method of sample preparation using RPTLC for the isolation of naturally occurring coproporphyrin-free carboxylic acids. Accurate separation and quantification of the individual isomers I–IV were achieved with the help of ion-pair, HPLC and on-line detection of their excitation and emission fluorescence spectra. These results clearly demonstrated the potential of fecal coporphyrin I–IV isomer ratio for the diagnosis and differential diagnosis of hereditary porphyrias.

Lai et al.[156] proposed an reversed-phase high-performance thin-layer chromatography (RPHPTLC) method for analysis of free porphyrins for diagnosis of porphyria. These authors observed more than 12 distinct bands of different porphyrins by viewing the plates under long-wavelength UV light. Simultaneous fluorescence detection of fecal urobilins and porphyrins by RPHPTLC

has also been published by Lam et al.[157] Silica gel TLC of free porphyrins for diagnosis of porphyria has also been reported by Handersan.[158] The distinct porphyrin bands were observed under long-wavelength UV light.

Porphyrins exhibit UV spectral absorption bands in the range 400–408 nm. On silica gel, the porphyrin fluorescence may be enhanced by dipping plates in a solution of dodecane–hexadecane–chloroform (1:1:18). The porphyrins can easily be detected in femtomole amounts on reversed-phase (RP) plates with λ_{ex} 404 nm and λ_{em} 560 nm; the calibration graph is linear between 0.15 and 3.0 pmol.[2,11]

5.8 Prostaglandins

PGs are one of the most biologically active family of compounds. They are unsaturated C_{20} fatty acids with a cyclopentane ring. Derivatives that contain this structure (PGs, prostacyclins, and thromboxanes) are known collectively as prostanoids. They occur in the nanogram or even picogram range in human tissues and body fluids. They have diverse biological action. Their full physiological role is not completely understood. A range of methodologies has been used for estimation of PGs in clinical laboratories. These include immunological assays, chromatographic techniques, and GC/MS.[159–165] Often HPLC, GLC, and GC/MS are used for quantitative measurement of PGs. Analyses of PGs by GLC and GC/MS involve sample extraction, thin-layer chromatographic purification, and derivatization. The overall procedure is time-consuming. Sample pretreatment is also essential in analysis of PGs and is mainly performed by using Sep-Pak™ columns[159,166] or styrene–divinylbenzene cross-linked copolymeric macroreticular ion-exchange resin XAD-2 as the solid-phase support.

Silica gel TLC is also used in analysis of PGs either as an analytical method or a cleanup procedure.[11] Raajmakers[167] proposed a TLC method for separation of all PG groups from pure substances using chloroform–methanol–acetic acid–water as a mobile phase. Tsunomoto et al.[168] describe a two-dimensional TLC procedure using ethylacetate isooctane–acetic acid–water (11.5:2:10) and chloroform–methanol–acetic acid (90:8:6) for separation of prostacyclin (PGI2) and thromboxane A2 (TxA2). These compounds are known to be involved in hemostases and oncogenesis. Various PGs (PGE2, PGE1, PGE2, PGA1) and some arachidonic acid metabolites were separated on silica gel modified with phenylmethylvinylchlorosilane RPTLC plates.[2] Alvarez Perez et al.[169] advocated TLC for the presence of PGE2 in normal and inflamed gingiva. Vasodilator PGE2 analogs[11] were separated either on silica gel G with chloroform–methanol–acetic acid (18:2:1) mobile phase or RP-12 plates with acetonitrile–water (35:65). Combinations of TLC and GC/tandem mass spectrometry (GC/MS/MS) or TLC, HPLC and GC/MS have been reported by several researchers for separation of PGs in biological samples.[162–165] Other recommended solvent systems[2] used for separation of major PGs are chloroform–isopropanol–ethanol–formic acid (45:50:0.5:0.3) and ethyl acetate–acetone–acetic acid (90:5:1). Most of the spray reagents used for detection of PGs following TLC separation, for example, concentrated sulfuric acid, PMA, 2,4-dinitrophenyl hydrazide, anisaldehyde/sulfuric acid, acidic ceric sulfate, and vanillin/phosphoric acid/ethanol are destructive. Nondestructive methods for detection include the use of iodine vapor spray and 8-hydroxy-1,3,6-pyrene-trisulfonic acid trisodium salt.[170] To improve detection limits, 4-bromomethyl-7-methoxycoumarin derivatives have been proposed for samples containing PGs.[171]

5.9 Steroid Hormones

Steroid hormones play a vital role in the human organism. They are defined by their physiological functions. The levels of the active steroid hormones in serum and their elimination products in urine are of great clinical significance. Glucocorticoid hormones contribute to adipogenic activity in human serum. Addisons' disease is caused by glucocorticoid deficiency and excessive secretion results in Cushings' syndrome. Estrogenic steroid concentrations in human urine are very important during pregnancy. Progesterone is also involved in the preparation and maintenance of pregnancy. Increased urinary levels of pregnane-3α, 20α-diol and allopregnane-3α, 20α-diol have been observed in early pregnancy. Elevation of 6β-hydroxycortisol is seen in human urine during pregnancy and in cases of hyperadrenocorticism. Urinary aldosterone is assayed to identify patients with hyperaldosteronism.[172] The urinary excretions of andro- and glucocorticoidenesis metabolites have also been studied in patients with gastric cancer.[173] Furthermore, dehydroepiandresterone, and in particular eticholanolone excretions were found to decrease significantly in the urine of women affected by malignant breast disease.[174]

PC, mainly TLC, is widely recognized for steroid analysis in clinical laboratories. Like other compounds, sample preparation is also necessary prior to TLC of steroids. Sample preparation is mainly done by enzymatic and acidic hydrolysis followed by liquid–liquid or liquid–solid extraction. Tang and Crone[175] have developed an efficient, effective, and inexpensive method for hydrolyzing steroid conjugates. Venturelli et al.[176] have suggested an improved multistep procedure for urinary testosterone analysis.

Silical gel is an effective sorbent for separating steroids. Several books and reviews dealing with the PC of steroids have been published.[2,6,7,11,177–179] Separation of urinary steroid hormones on silica gel have been studied in various mobile phases:[2,6,7,11] estrogens in butyl acetate–benzene (85:15), benzene–acetone (90:10), chloroform–ethyl acetate (80:20), chloroform–methanol–water (94:6:0.5); pregnanediol and pregnanetriol in chloroform–acetone (80:10) and chloroform–acetone–methanol (75:15:10); androgens in dichloromethane–methanol–water (225:15:1.5) and light petroleum (37–55 °C)–diethyl ether–acetic acid (48:50:2); corticosteroids in chloroform–methanol (98:2); and glucocorticoids in chloroform–dioxane–methanol (15:4:1). Other effective systems for separation of major estrogens, androgens, and pregnones are chloroform–acetone (9:1) and cyclohexane–ethylacetate–ethanol (77.5:20:2.5). Some researchers have also used two-dimensional and multidimensional development modes for separation of steroids.[180,181]

Tomosova[182] has published a method for analysis of urinary 17-oxosteroids labeled with dansylhydrazine by SPE on a C_{18} minicolumn and silica gel TLC with chloroform–methanol (97:3) mobile phase and scanning of fluorescence. Vingler et al.[183] reported a direct quantitative digital autoradiography thin-layer chromatographic method for separation of eight major androgens derived from testosterone metabolism. The separation was achieved on silica gel plates containing a fluorescent indicator and a concentration zone, and involved two different methods. The first method consisted of a double run using a mobile phase composed of dichloromethane–diethyl ether (90:10) and the second involved a double run with the same mobile phase followed by a second run at 90° with a mobile phase containing of toluene–ethyl acetate (50:50) when a single spot was to be run or toluene–ethyl acetate (70:30) when two tracks were to be run. Fenske and Schonheiter[184] used a silica-coated aluminum sheet separation and elution of glucocorticosteroids and sex steroids prior to radioimmunoassay. Agarwal et al.[185] have reported the TLC separation of regioselective and stereoselective androgen metabolites.

The introduction of alkyl-bonded plates has given rise to new experimental procedures in the PC of steroids. Watkins et al.[186] reported a method for the identification of estrogens on RP-18 and RP-8 layers with the ion-pairing mobile phase methanol–0.5% tetramethyl ammonium bromide solution in water (45:55 or 50:50). Lamparcyzk et al.[187] described methanol–water to be the best solvent system for separation of steroid hormones by RPHPTLC. Diol-bonded and cyano-bonded silica plates also permitted good separations of major estrogens and androgens.

Various spraying reagents have been used for locating steroids in situ. Most of them have been adequately discussed by Lamparczyk[178] The most popular spraying reagent used for detecting steroids is 10% sulfuric acid in methanol, followed by heating for 10 min at 90 °C and fluorescence scanning λ_{ex} 366 nm and λ_{em} 509 nm for quantification. Other recommended reagents are rubeanic acid, a mixture of copper sulfate and *o*-phosphoric acid, fast violet-salt B, manganese(II) chloride with subsequent heating at 120 °C and scanning at 366 nm, or charring of steroids on ammonium sulfate preimpregnated plates after a *p*-toluene sulfuric acid spray. Spraying with 0.1 mM 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in toluene–acetic acid (70:30) and densitometry have been found to be very sensitive for estriol 16β-glucuronide determination. New chromogenic reagents for detection of steroids are: 25% solution of tribromoacetic acid in chloroform, *p*-chloranil, *p*-fluoranil, and 2,3-dichloro 5,6-dicyanobenzoquinone.[7] Moreover, coupling devices[11] have also been advocated for detection and identification of steroids.

5.10 Other Compounds of Clinical Interest

Other compounds of clinical interest are gangliosides,[188] cerebrosides,[93] purines, pyrimidine, derivatives of nucleic acid,[189–192] and urinary organic acids.[193,194] These have been analyzed by TLC in various laboratories.

6 CONCLUSION

In the light of above discussions, it may be seen that considerable advancements have taken place in the area of PC technique. These include chromatographic separations, methods of detection, instrumental TLC, and hyphenated instruments. Thus the use of PC technique in clinical chemistry has widened. Much more advancement is expected in the near future.

ABBREVIATIONS AND ACRONYMS

AMD	Automated Multiple Development
FID	Flame Ionization Detection
FTIR	Fourier Transform Infrared Spectrometry
GC	Gas Chromatography
GLC	Gas–Liquid Chromatography
HIV	Human Immunodeficiency Virus
HPLC	High-pressure Liquid Chromatography
HPTLC	High-performance Thin-layer Chromatography

LLE	Liquid–Liquid Extraction
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NPTLC	Normal-phase Thin-layer Chromatography
PAF	Platelet Activating Factor
PC	Planar Chromatography
PG	Prostaglandin
PMA	Phosphomolybdic Acid
PMD	Programmed Multiple Development
PTH	Phenyl Thiohydantoin
QC	Quality Control
QTLC	Quantitative Thin-layer Chromatography
RP	Reversed Phase
RPHPTLC	Reversed-phase High-performance Thin-layer Chromatography
RPTLC	Reversed-phase Thin-layer Chromatography

Point-of-care testing (POCT) is defined as testing at or near the site of patient care, wherever that medical care is needed. The goal of POCT is to facilitate immediate evidence-based medical decisions that improve patient outcomes and reduce patient acuity, criticality, morbidity, and mortality, especially during life-threatening crises and emergency resuscitations. POCT is efficient and efficacious because it facilitates rapid diagnosis, faster treatment decisions, high-quality trend monitoring, and patient and physician satisfaction. New point-of-care (POC) technologies are appearing rapidly. This article summarizes principles and analytical methods of whole-blood analysis (WBA) for chemistry, hematology, and hemostasis analytes, cardiac injury markers, and other POC diagnostic tests. Then, the article discusses important clinical aspects, including test clusters and medical indications, methods of monitoring and enhancing performance, and optimization strategies. In the next two decades, diagnostic testing will continue to shift to the POC, necessitating collaborative integration, information consolidation, and Knowledge Optimization® in surgery, intensive care, emergency medicine, public health, and other settings extending from the acute care center to the patient's home.

1 INTRODUCTION

1.1 Definition of Point-of-care Testing and the Hybrid Laboratory

POCT is defined as *diagnostic testing at or near the site of patient care, wherever that medical care is needed*.[1] This broad definition, which includes near-patient testing, derives from the historical roots of the paradigm shift.[2] POCT is performed outside the main laboratory within the hospital, in clinics, and at various other distributed sites (Table 1). POCT facilitates rapid diagnosis, faster treatment decisions, high-quality trend monitoring, and patient and physician satisfaction. The clinical integration of POC analyzers at the site of patient care created the *hybrid laboratory*.[3,4] POCT, customized test clusters, minimized therapeutic turnaround time (TTAT), optimized diagnostic–therapeutic strategies, and, especially, *an emphasis on improved patient outcomes* are the hallmarks of the hybrid laboratory (Table 2).

1.2 Goal of Point-of-care Testing and Objectives of the Article

The goal of POCT is *to facilitate immediate evidence-based medical decisions that improve patient outcomes and reduce patient acuity, criticality, morbidity, and mortality, especially during life-threatening crises and emergency resuscitations*. The objectives of this article are (i) to review the principles of WBA and other POC methods, which enabled the paradigm shift to POCT; (ii) to understand POC test clusters (test menus); (iii) to describe new mathematical–statistical approaches to monitor the performance of POCT; and (iv) to present strategies that optimize POCT in critical care and other settings, including disasters.

Table 1 Sites of POCT

- Hospital
  - Bedside (alternate/alternative, ancillary, decentralized, and waived testing)
  - Critical care workstations in the operating room, emergency department, and intensive care unit
  - Hybrid laboratory instrument sites
  - Modular plug-ins for intensive care systems
  - Near-patient testing locations (permanent, temporary, and mobile)
  - Patient-focused care centers
  - Patient monitoring stations interfaced with *ex vivo* and *in vivo* systems
  - Procedure suites (e.g. cardiac catheterization laboratories)
  - Satellite laboratories
- Outpatient
  - Clinics and specialty care centers
  - Home (e.g. self-monitoring of blood glucose)
  - Patient-focused care facilities (e.g. ambulatory surgery, heart center, and chronic care)
  - Physician offices
  - Urgent care centers
  - Wellness testing areas (e.g. screening)
- Rescue and unique locations
  - Emergency ground vehicles (e.g. ambulances)
  - Helicopter and fixed-wing aircraft for patient transport
  - Military field operations and battlefields
  - Patient travel including remote and inaccessible locations
  - Points of disasters and emergency rescues
  - Ships, submarines, and other nauticals
  - Space shuttles and space station

Table 2 The hybrid laboratory – emergence and definition

Conventional laboratory (1980s)	Hybrid laboratory (1990s)	Personalized laboratory (21st century)
Centralized	Patient focused	Mobile
Separate samples	Critical care profiles (test clusters)	Quantitative diagnostic and therapeutic indices
Confusion	Whole-blood priority	Alternative sample types (e.g. saliva, interstitial fluid)
Slow, high-volume panels	Fewer, more important tests faster	Multiplex sample testing, and multimarker tracking
Data overload	Diagnostic synthesis	Wireless network
Laboratory turnaround time	TTAT	Optimized decision cycles
Cost analysis by function	Cost effectiveness from patient outcomes	Efficient global healthcare
Highly vulnerable during disasters	Reduced risk of failure	Small-world networks prepared for newdemics

2 PRINCIPLES AND ANALYTICAL METHODS FOR POINT-OF-CARE TESTING

2.1 Analytical Methods for Chemistry Analytes

2.1.1 Overview

Table 3 outlines common measurements and principles currently used *in vitro* for WBA. Biosensors found in whole-blood analyzers include the ion-selective electrode (ISE), substrate-specific electrode (SSE), analyte-specific optical sensor (ASOS), and electrical conductance sensor (ECS). The acronym ISE refers to measurement of cations (e.g. K^+) as well as anions (e.g. Cl^-). The term SSE

Table 3 Principles of biosensor-based whole-blood measurements

Analyte	Principle(s)
Ca^{2+}	ISE
Mg^{2+}	ISE
K^+	ISE
Cl^-	ISE
Na^+	ISE
pH	ISE or ASOS
pCO_2	CO_2 sensitive buffer pH electrode or ASOS
Total CO_2	Acidification of sample with pH end point by ISE
pO_2	Amperometric or ASOS
Glucose	SSE
Lactate	SSE
Urea nitrogen	SSE
Creatinine	SSE
Hematocrit	ECS

ASOS, analyte-specific optical sensor; ECS, electrical conductance sensor; ISE, ion-selective electrode; SSE, substrate-specific electrode.

was introduced in 1991[5] and refers to the measurement of glucose, lactate, urea nitrogen, creatinine, and other metabolites. ASOS was introduced recently[6] to describe clinical optical sensors. Most POCT instruments also include hematocrit measurement performed with an ECS or hemoglobin measurement by CO-oximetry or some other method. Some instruments include fiber optics for multiple wavelength measurement of O_2 saturation. *In vitro* instruments use sensors to measure several analytes simultaneously and quickly. *Ex vivo* and *in vivo* blood chemistry monitoring systems generally are limited to relatively few analytes, primarily those that vary rapidly and require fast response or frequent measurements. These analytes include oxygen saturation, glucose, blood gases (partial pressure of oxygen, pO_2; partial pressure of carbon dioxide, pCO_2), pH, potassium, sodium, ionized calcium, hematocrit, and, to a lesser extent, urea, creatinine, and lactate. Most effort has been devoted to the development of *ex vivo* and *in vivo* systems that monitor these analytes in the hospital environment, particularly in the operating room and intensive care unit.[7,8] Glucose also is the focus of ongoing attempts to develop a wearable or implantable monitoring system for outpatient use by diabetics. The next sections briefly discuss the measurement principles of electrochemical, fiber optic, and relatively new fiber-optic chemical sensors. Miniaturized electrochemical and fiber-optic sensors are found in POCT devices and are used in intermittent and continuous monitoring systems as well.

2.1.2 Sensors

Electrochemical sensors fall into two categories: potentiometric and amperometric. Most potentiometric sensors use an ion-selective membrane that incorporates a specific ionophore into the membrane matrix. The membrane functions as the biodetector of the electrode. When in contact with blood or other body fluids, the ionophore selectively interacts with a target ion species and creates an electrical potential across the membrane. This potential is measured between the internal reference electrode and the external reference electrode. The potential is logarithmically proportional to the activity of the ion that is being measured in the sample. In some systems, measurements must be corrected for interference (e.g. correction of Mg^{2+} for Na^+, Ca^{2+}, and pH in the sample). Whole-blood analyzers commonly use ISEs for the measurement of electrolytes and pH *in vitro*. A modification of the basic potentiometric sensor, the Stowe–Severinghaus electrode, is used to measure pCO_2. In this electrode, CO_2 from the sample being measured diffuses across a CO_2-permeable membrane into a bicarbonate buffer that is in contact with a pH sensor. When the CO_2 reaches equilibrium in the bicarbonate buffer, the pCO_2 of the sample can be calculated on the basis of the pH measured in the buffer. A related principle is used to quantitate total carbon dioxide (TCO_2) content in whole blood after automated addition of acid to displace bound CO_2.[9]

The response of potentiometric sensors is logarithmic. Therefore, small errors in the measured potential produce large errors in the results. These errors will affect both accuracy and precision. If there is a change in activity from a_1 to a_2, there will be a change in the sensor potential. If $\Delta E = E_2 - E_1$, it follows from the Nernst equation that $\Delta E = [(RT \ln 10)/(ZF)]\log[\text{ratio of the activities}]$, where R is the gas constant ($8.31431\,J\,K^{-1}\,mol^{-1}$), T is the absolute temperature (K, kelvin), ln 10 is the natural log of 10 (2.303), F is the Faraday constant ($96\,487\,C\,mol^{-1}$), and Z is the valence (charge) of the ion. When ΔE is 1 mV, T is 310.15 K (37 °C), and Z is 1, the ratio of the activities will be equal to $\log^{-1}[(\Delta E)/((RT \ln 10)/(ZF))] \approx \log^{-1}[1\,mV/61.54\,mV] = 1.038$. Hence, a ±1 mV change in the measured potential is equivalent to approximately a ±4% change in the reported value. The reference electrode alone can introduce uncertainty of up to ±0.5 mV from junction potential, sample matrix, and boundary layer phenomena where the electrolyte enters the sample flow path. This is equivalent to a change in the accuracy of approximately ±2% for monovalent ions (i.e. $Z = 1$ and $\log^{-1}[0.5\,mV/61.54\,mV] \approx 1.019$) or approximately ±4% for divalent ions (i.e. $Z = 2$ and $\log^{-1}[0.5\,mV/30.77\,mV] \approx 1.038$). Instabilities during the electronic measurement of the potential of the sensor

Figure 1 Cross-sectional schematic of a Clarke-type electrode. This figure illustrates a typical Clark electrode for measuring pO_2. The anode generates the electrons to drive the reaction at the cathode where oxygen is converted into water.

electrochemical cell (ISE :: reference electrode) and electrical noise coming from sensor modules or *in vivo* probes detract from the precision of the analyte readings. Inaccuracy and imprecision combine to produce time-variant changes in calibration. As a consequence, *ex vivo* and *in vivo* monitors must either be designed for very high stability or else incorporate periodic recalibrations to correct for this drift.

Amperometric sensors generally are based on the Clark-type oxygen electrode (Figure 1).[10] A barrier membrane placed over the sensing electrode allows oxygen from the sample to diffuse to the electrode, but excludes chemical species that potentially could interfere with electrode function. A voltage applied across the sensing and reference electrodes reduces oxygen and, at steady state, generates an electrical current that is linearly proportional to the pO_2 in the sample. A common enzyme-based amperometric sensor is the glucose SSE. Immobilized glucose oxidase (GO) oxidizes the glucose substrate. Several different approaches have been used to quantitate this oxidation reaction and to determine substrate concentration. These include oxygen consumption, which requires an additional reference oxygen sensor, and hydrogen peroxide generation, which does not. Measurement of the latter is more practical, in view of sensor space constraints. There are many different glucose SSE designs. Some use an electron shuttle and glucose dehydrogenase (GD)[11] to reduce dependence on O_2. Barrier membranes of various configurations are used to exclude interfering species, select for the target substrate, and control the rate of diffusion of the substrate into the sensor. For amperometric sensors, in general, slight changes in membrane permeability or in the electrodes over time can cause drift in the output current. Therefore, for monitoring applications, SSEs also must be designed for high stability or be recalibrated periodically.

Optical sensors differentiate oxygenated blood from deoxygenated blood by spectrophotometry. A narrow waveband light source such as a light-emitting diode (LED) generates light that is transmitted down optic fibers to the tip of a catheter or finger sensor (e.g. pulse oximeter). Light reflects from the blood back through one or more optic fibers to a photodetector. Several wavelengths are chosen such that the differential absorption characteristics of oxyhemoglobin and hemoglobin allow determination of the ratio between the two. Fiber-optic chemical sensors, also referred to as *optodes*, have received considerable attention as a technology that has potential advantages over more conventional electrochemical sensors for automated monitoring. Optodes can be made very small, require no direct electrical connection to the patient, are free from electromagnetic interference, and can incorporate internal referencing to reduce or eliminate drift. On the other hand, commercial experience to date has shown that they can be difficult and costly to manufacture and have low production yields. Four basic approaches to fiber-optic chemical sensors have been described, including absorption, fluorescence intensity, fluorescence lifetime, and surface-enhanced Raman spectroscopy (SERS). Commercial systems are based primarily on either absorption or fluorescence intensity. With both approaches, light is passed through an optic fiber to the sensor that contains an indicator. In absorption sensors, the target analyte is measured by the intensity of the color of the indicator, which changes in

proportion to the analyte concentration. In fluorescence intensity sensors, it is the intensity of a lower wavelength light reemitted by an indicator that changes in proportion to the analyte concentration. Most developmental work with optodes has focused on pO_2, pCO_2, and pH, although fiber-optic sensors for glucose and electrolytes have also been described.

2.1.3 *Transportable, Portable, and Handheld Instrument Formats*

Table 4[12–21] lists whole-blood analyzers and biosensor-based tests that they perform. Biosensors allow simultaneous direct measurement of several indicators of vital functions in one whole-blood sample within 1–2 min. Competition is stimulating companies to expand test menus and to extend linear ranges of the biosensors to better cover critical analyte levels. Transportable instruments are larger whole-blood analyzers that can be placed on carts with uninterruptable (battery) power supplies for short-term operation. These instruments have several advantages, such as the selection of user-defined test clusters (critical care profiles) from large menus of tests, automation with few manual sample processing steps, selectable minimum sample volumes, fast analysis cycle, high throughput, low operating cost per test, long-lasting reagent supply, and self-contained biohazard waste storage. Portable instruments vary in size from dimensions equivalent to personal computers to dimensions nearly comparable to handheld devices. These formats display a wide variety of design features including fiber-optic measurement and multiple- or single-use (unit use) cartridges. Cartridges have self-contained calibrants and reagents for testing. In some cases, for blood gas measurements, solutions in the cartridges are equilibrated with appropriate gas tensions for the calibration of pO_2 and pCO_2. Although a means of temperature control (37 °C) has to be built in, no external gas tanks are required. Hence, bulk and weight are reduced, and mobility is increased significantly. Portables usually have convenient handles for carrying and occupy modest footprints. Other advantages include biohazard containment and battery operation, with the option for benchtop use with conventional power. Test menus generally are limited and operating costs usually are higher compared to transportables. Handheld devices have the advantages of interchangeable test cartridges, convenience, small size, light weight, compact storage, and battery operation. A handheld device can be placed in one hand, while the other hand is free to insert a cartridge or to apply a blood sample with a syringe. Miniaturization of the test cartridge is the result of microfabrication. Chip-based technologies eventually will lead to large test menus in handhelds. Global use of small handhelds will reduce costs.

2.1.4 *Handheld Glucose Monitoring*

The most common handheld bedside device is the glucose meter. Most glucose monitoring systems (GMS) utilize either (i) electrochemistry (amperometry or coulometry), or (ii) photometry. Both methods depend on enzymatic reactions to generate a signal, which correlates to the sample glucose concentration. Table 5 lists representative chemical principles of glucose test strips used in the handheld meters found in Table 4. Most glucose meters today rely on electrochemical methods to measure glucose (Figure 2). Glucose meters typically use a whole-blood sample (arterial, venous, or capillary). Transdermal glucose meters (i.e. GlucoWatch) have been developed to sample interstitial fluid through the skin via reverse iontophoresis.[10] However, these meters have been discontinued by the manufacturer. More recently, continuous glucose monitors have been introduced. Both devices require confirmation of accuracy with a conventional glucose meter. Although promising, both the noninvasive transdermal and continuous glucose monitoring systems are not recommended for routine use in the clinical environment due to limited data from clinical studies.[22,23]

While bedside and home glucose testing represents the standard of care for diabetics, glucose meters must be used with caution in critical care because of potential random and systematic errors. This is a major concern due to the increased use of handheld GMSs for tight glycemic control (TGC).[24,25] TGC protocols require hourly or continuous monitoring to adjust insulin infusion regimens. Figure 3 shows TGC ranges from TGC protocols reported in literature or current use by hospitals.[24–34]

Glucose results must be interpreted in light of regional metabolism, blood supply, and specimen source (if venous or capillary), as well as the patient's clinical status. Additional clinical research and validation will be necessary to identify the relative importance of intrinsic and extrinsic interferences (e.g. confounding factors) and determine if results obtained with glucose meters are accurate enough to successfully guide insulin therapy in critical care patients.

These interferences or "confounding factors" are grave concerns in critical care glucose monitoring. As stated, they are either intrinsic or extrinsic in nature (Figure 2). Intrinsic factors include specific physiological elements, such as hematocrit, blood pO_2, blood pressure, sample source (venous, arterial, or capillary), pH, temperature, and the blood matrix (water, lipid, cellular, and protein contents).[35] Extrinsic factors include drug interferences, user error, and harsh environmental conditions.

Hematocrit. The proportion of red blood cells relative to plasma has an inverse effect on measured glucose. Tang et al. found increases in hematocrit decreased glucose meter readings.[36] Conversely; decreases in hematocrit were found to increase glucose values. The mechanisms that cause this effect may be diffusion related or mechanical in nature. High hematocrit can decrease the amount of glucose that diffuses into the biosensor. The large amount of red blood cells in high hematocrit samples may mechanically impede the biosensor and reduce glucose readings. Low hematocrit samples facilitate increased diffusion of glucose toward the biosensor, thereby leading to higher readings on the GMS. Some manufacturers address the hematocrit problem by prelysing red blood cells before testing (HemoCue) or by compensating for hematocrit effects through test strip design coupled to software algorithms (StatStrip) (Figure 4).[35]

pO_2 effects. Critically ill patients may be on oxygen therapy; therefore blood pO_2 levels may be higher than normal. Originally, GO-based systems showed inaccuracies at extreme pO_2 levels. This was common in systems that relied on reactions that generated a hydrogen peroxide (H_2O_2) intermediate. Hydrogen peroxide then disassociates into hydrogen ions, oxygen, and electrons (used to measure glucose).[37] As pO_2 increased (>100 mm Hg), the disassociation reaction would become less favorable, thus causing lower glucose readings. Recent GO-based systems (e.g., StatStrip, NOVA Biomedical, Waltham MA) use a modified GO enzyme method that alleviates pO_2 effects, thereby minimizing this confounding factor.[35] The opposite

GD, glucose dehydrogenase; PQQ, pyrroloquinoline quinone; GO, glucose oxidase; FAD, flavin adenine dinucleotide; H_2O_2, hydrogen peroxide; MBTH, *meta*(3-methyl 2-benzothiazolinone hydrazone)-*N*-sulfonyl benzenesulfonic acid; HRP, horseradish peroxidase; ANS, 8-anilino-1-naphthalenesulfonic acid.

may also be true, where low pO_2 (<40 mmg Hg) can affect glucose results by 15% when using GO-based systems.[38]

Hypotension and hypoperfusion. Sylvain et al. showed GD-based systems to have significantly different results ($P < 0.001$) when testing capillary whole-blood samples from hypotensive patients in comparison to a reference analyzer.[39] GO-based systems showed similar results. In contrast, venous samples tested on GMSs did not show statistically significant differences when compared to venous samples tested on laboratory analyzers.

Sample source. Capillary blood is the most common sample type used by POC GMSs. Several studies have shown variations in accuracy when comparing capillary versus venous blood samples.[40] Recent GMSs showed greater accuracy with arterial samples compared to capillary blood; however, older GMS models showed similar results between the two sample types. Results derived from venous blood samples exhibited improved accuracy compared to capillary blood for GD-based GMSs. Alternate site testing must be considered as well in evaluations of accuracy and may be system dependent.

Specimen matrix. Water, lipid, protein, and cellular content may also be confounding factors. Glucose is more

Figure 2 Glucose/lactate electrochemical-based biosensor. Glucose biosensor interferences affect various biosensor layers. Oxidative or reductive reactions typically interfere at the electrode. Blood oxygenation may affect older glucose oxidase–based systems that depend on an oxygen intermediate to generate electrons. Matrix and hematocrit effects interfere with glucose diffusion rates, thereby altering the amount of glucose detected.

Figure 3 Tight glycemic control ranges as used in hospitals and reported in literature.

Figure 4 Schematic of a glucose meter test that automatically adjusts for hematocrit effects, and interference from oxidizing agents. Patents 6,287,451/6,837,976/EP 1 212 609/CA 2,375,092.

soluble in water; therefore, high plasma water content can cause higher glucose readings.[41] Lipid, proteins, and cellular components may impede photometric systems by increasing the turbidity of the sample. Such matrix effects may also alter the viscosity and hence reduce the glucose diffusion rate in both amperometric and photometric systems.

Drugs. Drugs that oxidize or reduce glucose biosensor electrodes may interfere with glucose results. Tang et al. conducted a study to determine the effects of 30 different

drugs on 6 different glucose meters.[42] High doses of ascorbic acid were shown to yield lower glucose values on GO-based systems. Acetaminophen caused increased glucose values in all tested GD-based systems and in some GO-based systems. High doses of dopamine increased glucose values in GD-based systems while mannitol increased glucose values in GO-based systems. More recently, icodextrin (osmotic agent for dialysis) has also been shown to generate falsely high results due to the drug being metabolized to maltose, which is indistinguishable from glucose on GD/PQQ-based instruments.[43]

pH and temperature. Since most GMSs convert glucose into a detectable signal via enzyme-catalyzed reactions, pH, and temperature may play a role in altering the enzyme kinetics, thereby causing errors. Kilpatrick et al. reported significant deviation in glucose measurements for samples with pH <6.95 and >7.85.[44] Temperature may also play a role. Oberg et al. suggests cold temperatures producing discrepant results; however, the effects of fever are currently unknown.[38,45]

Other factors. User error and environmental conditions may contribute to inaccuracies. Studies show the potential for operator error to still exist despite advances in more user-friendly instruments and protocols.[46] Over the years, environmental conditions have become more important due to the use of POC instruments under field conditions (e.g. disaster areas, war zones, and rural areas). POC instruments, including GMSs, were used on airborne hospitals to evacuate survivors after the Asian Tsunami of 2004.[47] In a separate study, Kost et al., identified conditions in post-Tsunami Thailand, and post-Hurricane Katrina New Orleans to be unacceptable for routine POC GMS use due to the high humidity and temperatures. This was supported by another study in 2007 that tested the robustness of POC instruments under certain environmental stresses.[48]

If glucose meter results are inaccurate, imprecise, or nonlinear in critical decision ranges, both medical and legal problems may arise, especially if undetected de novo onset of hypoglycemia, hyperglycemia, or diabetic ketoacidosis leads to an adverse outcome or if misleading results trigger inappropriate therapy, especially with TGC protocols.

2.1.5 *Pulse Oximetry*

Pulse oximeters are POC medical devices that noninvasively measures both the amount of oxygen in a patient's blood and changes in blood volume through the skin (Figure 5). These instruments consist of a clip that contains the photosensor, and two LEDs. One LED is red ($\lambda = 660$ nm) and the other emits light in the infrared range ($\lambda = 905$, 910, or 640 nm). The clip is placed on a part of the body, which is translucent to the light emitted by the LEDs (e.g. finger nail and ear). Some new instruments utilize forehead sensors to minimize interference.[49–51] Oxyhemoglobin absorbs more infrared light than deoxyhemoglobin. Conversely, deoxyhemoglobin absorbs more red light than oxyhemoglobin. Therefore, the oxyhemoglobin/deoxyhemoglobin ratio can be calculated on the basis of the amount of red versus infrared light detected by the photosensor. This ratio is then compared to stored reference tables within the instrument to generate oxygen saturation values. Pulsatile blood flow is measured by measuring the rising and decreasing amounts of absorbance that corresponds to blood volume. Absorbance is treated as a wave function where the resultant wave is used to calculate the changes in blood volume through the skin.

Figure 5 Pulse oximetry methods. Light sources emitting both red (650 nm) and infrared (850 nm) light are transmitted through the skin. Deoxyhemoglobin and oxyhemoglobin have different absorption profiles for red and infrared light. The photosensor calculates the ratio between red and infrared light and compares these values to correlation tables to derive an oxygen saturation level. Since blood flow is pulsatile, the photosensor will detect rises and falls in the red/infrared absorption ratios. The photosensor converts these absorption values into a wave function where the resultant is used to calculate the blood volume going through the skin.

Interferences. Pulse oximeters are susceptible to two types of interference due to (i) photointerference and (ii) hypoperfusion. Interferences have resulted in failure rates of 5–50%, and a potential reduction in sensitivity and specificity from 0.92 to 0.74 and 0.90 to 0.84, respectively.[52,53] Photo interference includes ambient light, sensor motion, surgical diathermy, and presence of either carboxyhemoglobin or methylene blue.[54–56] Hypoperfusion, as the result of cardiovascular disease, hypoxia, sepsis, or respiratory disease also contributes to error rates. In the end, interfering factors alter the detected light (e.g. absorption, refraction, reflection, and

constructive/destructive interference), which results in aberrant oxygen saturation results.

2.2 Analytical Methods for Hematology and Hemostasis Analytes

Table 4[12–21] summarizes representative POC devices, the physical principles of measurements, and the tests that the instruments perform. Generally, the devices use a drop of whole blood from a fingerstick or a venipuncture specimen that may be citrated depending on the method. For general information, please refer to the Clinical Laboratory Standards Institute (CLSI) guideline[57] that describes specimen preparation for coagulation tests. After reagent mixing, clotting of the blood sample in the reaction chamber produces a primary physical change that is detected either mechanically or optically. Measurements may also be performed noninvasively. For example, noninvasive hemoglobin monitoring was cleared by the Food and Drug Administration (FDA) in 2008 (Masimo, Limonest, France). Like the biosensor-based instruments in Section 2.1, instruments in Table 4 vary in size from transportable/portable to portable to nearly handheld, and correspondingly vary in convenience for use at the POC. For these types of instruments, electronic and whole-blood quality control are used to satisfy regulatory requirements. With these new POC technologies, one should evaluate test results for clinical endpoints in specific patient situations in parallel with test results obtained with conventional hematology and hemostasis methods in the parent (main) laboratory. Some new methods produce results that are linearly related or standardized to traditional methods. However, because of the different principles of measurement, some do not. Use of a global standardization parameter, such as the international normalized ratio (INR) for reporting of prothrombin time (PT) results, is an essential strategy. Error can result from admixed tissue fluid when capillary specimens are used. Hence, alternative sources of specimens are more suitable for patients in intensive care.

ECSs involve applying an alternating voltage across two or more electrodes in contact with the fluid sample and measuring impedance (conductance) to the resulting current flow. This method is used to determine the hematocrit in whole blood. The conductivity is dependent on the volume of relatively nonconductive blood cells between the electrodes and on the electrolyte concentration in the blood. The electrolyte concentration can be approximated by the simultaneous measurement of the whole-blood sodium level to produce a more accurate estimate of hematocrit. Conductance-based measurements of hematocrit may not be accurate in patients given autologous blood transfusions where plasma has been largely replaced by crystalloid[58] or in surgery patients with variations in protein levels and osmolality.[59] Therefore, hematocrit determined by ECS must be interpreted with caution in critically ill patients, particularly those patients who receive intravenous therapy and blood products. Hematology analyzers based on electronic particle counting can have an advantage when there is abnormal protein level or osmolality.[13] Platelet function analysis is clinically valuable and is available on some devices. There is a need for both miniaturized hematology endothelial progenitor cells (EPC) instruments and platelet function analyzers for POCT in critical care settings.

2.3 Cardiovascular and Cardiac Injury Markers

The use of cardiac biomarker testing in the emergency department is one of the most difficult challenges faced by emergency medicine physicians today. Admissions of patients with low probability of acute coronary artery disease often times leads to excessive costs,[60] while release of patients with acute myocardial infarction has become the number one leading cause of malpractice lawsuits in the emergency department.

Generally, patient-focused clusters of markers, selected from cardiac troponin I (cTnI), creatine kinase-MB (CK-MB) isoenzyme, B-type natriuretic peptide (BNP), N-terminal pro-B-type natriuretic peptide (NT-proBNP), D-dimer and myoglobin represents a good diagnostic tool for both ruling in and ruling out acute myocardial infarction and related conditions.[61] cTnI, for example, has shown to be a highly sensitive and specific marker compared to myoglobin. It is suggested that the 99th percentile reference serves as a cutoff for the diagnosis of myocardial infarction in the emergency department.[62] Another marker, BNP and NT-proBNP, are also good heart failure biomarkers. Additionally, there is evidence that BNP is released due to ischemic events and thus may also serve as a marker for myocardial infarction.[60]

Several portable and handheld devices are available for POC measurement of cardiac injury markers. For example, one handheld device for the qualitative measurement of cTnI uses a solid phase chromatographic immunoassay, where the sample (200 μL) is transferred into the receptacle region containing monoclonal anti-cTnI antibody–dye conjugates and biotinylated rabbit polyclonal anti-cTnI antibodies. These antibodies bind to cTnI in the sample to form complexes that migrate through the reaction strip. The antigen/antibody–dye complexes are then captured by immobilized streptavidin in the cTnI zone. Additional protein–dye conjugates not bound in the cTnI area are later captured in the control area. Results are available in 15 min. Another handheld model tests for the cardiac isoenzyme of creatine kinase,

BNP, CK-MB, and myoglobin using analogous principles (Table 4). Other handheld or portable models measure cardiac injury markers quantitatively, simultaneously, and quickly (in a few minutes).[60]

The National Academy of Clinical Biochemistry guidelines recommend cardiac biomarker testing instruments to have a high clinical sensitivity and specificity to facilitate early diagnosis of acute myocardial infarction. No signal marker meets all of these criteria; therefore, the multianalyte approach has the most merit.[60] New specific markers are also needed. Future markers may include heart fatty acid–binding protein, myeloperoxidase, ischemia-modified albumin, and soluble CD40 ligand.

POC cardiac biomarker testing is generally recommended at institutions that cannot deliver biomarker TATs of ~1 h. However, faster TAT is more efficient for patient care paths. Laboratory personnel must be involved in the selection of these devices, the training of individuals to perform analysis, the maintenance of POC equipment, verification of the proficiency of operators on a regular basis, and the compliance of documentation with requirements by regulatory agencies.[23,63]

As time progresses, the standard of care for timeliness for biomarker testing will also shift toward faster turnaround times (Figure 6). Contemporary timeliness in critical care testing has set a continuum precedent for chest pain centers that now consider 15 min as a reasonable criterion for accreditation. However, cardiac biomarker results should be available within 30 min, the preference stated by ACC/AHA guidelines.[10,64]

2.4 Immunoassays

Like in cardiac biomarker testing, antibodies can be used to target disease-specific molecules. Devices and test kits are available for the evaluation of patients with metabolic (e.g. β-hydroxybutyrate for diabetes mellitus), infectious (e.g. human immunodeficiency virus, HIV), and other diseases. Samples may include whole blood, sputum, and stool. Other methods include less-invasive or noninvasive samples including urine or saliva to detect sexually transmitted diseases and HIV, respectively.

POC infectious disease tests are predominantly based on immunoassays. Reagent cards, test kits, or swabs are common test formats. Table 6 provides a list of current POC infectious disease tests. Over the years, the convenience and accuracy of POC infectious disease tests has led to increased acceptance by the medical and public health community. In 2006, the Center for Disease Control and Prevention issued a recommendation for POC saliva-based screening for HIV in all Americans from age 16 to 64.[65] With the threat of avian influenza, rapid POC tests for H5N1 and H7N7 strains are being developed to screen patients. Current POC influenza tests may not be specific enough to discern between nonavian versus avian influenza. If not rectified, this lack of sensitivity and specificity may contribute to the spread of a pandemic.[66,67]

Figure 6 Standards of care for cardiac biomarker testing. The standard of care for timeliness of cardiac biomarker testing. Forceful clinical drivers mold the shape of the rapid response curve while the underlying performance vector enables it, aiming at optimization, first discrete, then in the future, continuous. Contemporary timeliness in critical care testing has set a continuum precedent for chest pain centers, which now consider 15 min as reasonable criterion for accreditation. However, all cardiac biomarker results should be available within 30 min, the preference stated in ACC/AHA guidelines.

Table 6 POCT for infectious diseases

Disease/ pathogen	Device or test	Manufacturer	Format/ method	Sample
Adenovirus	Adeno-Strip	Coris Bioconcept	Disposable reagent kit	Stool
	Immunocard Adenovirus[a]	Meridian Bioscience	Disposable reagent card	Stool
Avian Flu (H5N1, H7N3) flu	Multiplexed POC/flu tests[b]	In development	Chip[b](UCol), others	Depends on method

2.5 Point-of-care Molecular Diagnostics

Nucleic acid amplification testing (NAAT) methods using polymerase chain reaction (PCR) provide highly sensitive and specific tools at the POC. PCR utilizes DNA polymerases (taq polymerase for DNA or reverse transcriptase for viral RNA) to amplify a target sequence. The amplified genetic materials (i.e., amplicons) are detected using fluorescent probes or absorbance (e.g., turbidity). Coupling of fluorescent-based detection and melting point analysis allows for target differentiation and quantitation. Handheld and transportable PCR-based POC instruments have appeared in the past decade for biowarfare detection (e.g. toxins and pathogens). More recently, in the clinical environment, multiplexed PCR-based bench top systems have been developed to

Figure 7 Polymerase chain reaction–based detection of pathogens. Heat (Δ) is used to denature DNA strands. Specific primers bind to target sequences to allow DNA replication by DNA polymerase (DNA pol). Fluorescent probes are used to detect specific target sequences in the amplified DNA. Fluorescent resonance energy transfer (FRET) can be coupled to melting point (T_m) analysis to provide further differentiation between DNA sequences, thereby allowing for multiplexed pathogen detection.

detect pathogens in patients suspected of having sepsis (Figures 8 and 9).[68]

Multiplex PCR NAAT. Existing instruments such as SeptiFast (Roche Diagnostics, Grenzacherstrasse, Switzerland) provide multiplex detection of 25 different gram positive, gram negative, and fungal pathogens. SeptiFast has been shown to detect additional organisms compared to blood culture in blood samples collected in parallel.[68] (Figures 7–9) PCR-positive results may reflect a real infection. Collectively, 60 patients had PCR and/or blood culture positive results, and 140 negative PCR and blood culture results. Polymicrobial bloodstream infections were identified in nine cases. In all four PCR-positive cellulitis cases, PCR detected a pathogen that was not found by blood or other cultures. Thirty-two PCR- and blood culture–positive cases of coagulase negative *Staphylococcus* cases were judged as a contaminant by clinical referees.

Other NAAT. As technology improves, we will see more molecular-based pathogen detection as seen with the PCR-based system approved by the FDA for screening group B *Streptococcus* infections in newborns.[69] Other non-PCR-based tests have emerged such as loop-mediated isothermal amplification (LAMP). LAMP amplifies nucleic acid using multiple primers at a single temperature (63 °C) in less than 1 h. The rapidity and isothermal nature may allow this technology to be applied to disaster and field NAAT.

2.6 Criteria for Instrument Evaluation and Selection

The most important practical criterion to consider when choosing an instrument for POCT is its medical efficacy (Table 7). Test clusters (test menus) should be patient focused and facilitate medical decision making. The standard of care for rapid response testing is evolving. A TTAT of 5 min is achievable with POCT and now is expected during critical emergencies.[1] Speed should be accompanied by cost effectiveness.

Figure 8 The Venn diagram shows the distribution of PCR and blood culture positive cases. The distribution of cases is based on the comparison of PCR to blood culture results collected at the same time point.

Economic efficacy is measured in terms of various outcome metrics, such as professional productivity and length of stay in critical care. It is important to establish the viewpoint of economic justification with respect to site (e.g. the intensive care unit), diagnosis (e.g. a particular diagnosis-related group), and/or outcome (e.g. the prevention of pseudohyponatremia). System features such as test flexibility, modularity, expandability, and upgrade capability, as well as instrument, consumable, and maintenance costs weigh heavily in the assessment of economic trade-offs. These features must match the workload and its pattern. For example, stationary analyzers with fast throughput may be preferred when there are several operators or bursts in test volume.

Conservation of patient blood volume depends on the specimen volume, type, and matrix (i.e. whole blood, plasma, or serum), and on the number of specimens that are required to perform a given cluster of diagnostic tests.

Figure 9 A value map showing the distribution of PCR-positive cases by clinical problem.

If only one or two analyte measurements are desired, it is an advantage if the instrument accepts a smaller sample volume compared to the sample required for the entire test menu. Blood loss from frequent diagnostic testing leads to unnecessary transfusion and ''hidden'' or ''downstream'' risks for the patient and the institution. Most POC devices use whole blood, which conserves volume and eliminates centrifugation. Elimination of processing steps saves time. Fast test results at the POC are most beneficial for the trending of an analyte that changes rapidly or unexpectedly, that is, has a short medical half-life, or for the rapid detection of life-threatening abnormalities. Results are outdated quickly by delays in transporting specimens to the main laboratory or by delays in processing plasma or serum for analysis. Outdated results encourage unnecessary repetition of testing and additional blood loss. Additionally, if an analyte has already been measured and its level is not changing, or if it is not important in medical decision making, there is no need to measure it at the POC. Wasteful duplication should be avoided. The net effect of these strategies is conservation of patient blood volume and institutional resources.

Table 8 also outlines design criteria for safety, ergonomics, security, and risk, as well as technical and quality features. Biohazard containment, space, storage, and disposal are especially important in intensive care. The design of a POC instrument should be ergonomic. Speed, ease, and security of operation are essential. Throughput must match clinical input, especially during resuscitations and emergencies, when there are bursts in testing volume that may overwhelm POC resources. Excellent on-site performance is essential if whole-blood analyzers are to be clinically effective. Handheld and portable instruments should be compact, reliable, durable, lightweight, and efficient, with streamlined requirements for quality control, maintenance, and reagents. Reagents must have adequate shelf life. Instrument operation should be straightforward with few preanalytical processing steps, and, therefore, less potential for error and biohazard exposure. In an emergency, the operator should be able to interrupt an automatic extended (two-point) calibration to save time. The pretest (one point) calibration cycle should be short. Calibration drift should be minimal. Programmability, self-diagnostics, data management, and simplicity are important, since operators with different levels of experience perform measurements. Whole-blood methods should not be sensitive to operator technique or to the type of clinical application (e.g. resuscitation, POC, mobile cart, or satellite laboratory). Whole-blood analyzers may be effective in a main laboratory if there is a fast transport system. Cautiously balance the location of testing, quality of measurements, format of instruments, and total operating expenses. On a per test basis, handheld instruments generally are less expensive to purchase but more expensive to operate, compared to transportables. Handheld instruments and their supplies also run the risk of theft and should be secured.

Table 7 Criteria for the selection and evaluation of POCT systems

- System performance
  - Accuracy, precision, bias, resolution, reproducibility, stability (biosensor drift), and response time
  - Linearity and performance in the high and low extremes of measurements, including critical limits
  - Consistency and relationship to tests performed in the parent (main) laboratory
  - Compatibility with other *in vitro*, and with *ex vivo* and *in vivo* whole-blood systems
  - Artifact elimination, error detection, interferences warning, and specimen flagging
- Technical and quality features
  - Throughput, automated calibration, interrupt capability, and duration of analysis cycle
  - Compact, reliable, durable, lightweight, mobile, and power efficient with battery operation
  - Reagent stability, shelf life, lot size, and variability (biosensor, calibrant, cartridge)
  - Continuous quality improvement (quality control, quality monitors, proficiency testing)
  - Number and efficiency of preanalytical and postanalytical process steps
  - Analytical performance with whole-blood and other sample types (e.g. CSF and body fluids)
  - Compliance with federal, state, and accreditation regulations and training requirements
- Qualification of new devices/tests and education/competency of operators
  - Protocols for evaluation and method comparisons (CLSI) to initiate new devices and tests
  - Instructions for meeting the requirements of federal, state, and voluntary accreditation agencies
  - Resources for education and competency (interactive, video, CD-ROM, virtual, Internet, or other)
- Connectivity, integration, and data storage/retrieval
  - Interfacing with physiological patient monitors in critical care areas
  - Remote review, remote control, robotics, and data management/overview system
  - Networking, interfacing (bidirectional), and wireless communications
  - Information systems, data storage, and archiving capabilities (LIS, HIS, CDR, CIS)
  - Compliance with accepted connectivity standards
- Safety, ergonomics, security, and risk
  - Biohazard control, containment, and disposal
  - Speed, ease, simplicity, and user-friendly operation
  - Identification, validation, notification, and security for operator and patient
  - Risk reduction features and on-site error minimization
- Conservation of patient blood volume
  - Specimen volume, type, and matrix (e.g. whole blood, plasma, or serum) accepted
  - Medically useful half-life of test results
  - Elimination of unnecessary transfusions and their risks
- Economic efficiency
  - Professional productivity and satisfaction
  - Impact on length of stay
  - Cost effectiveness by site, diagnosis, and/or outcome
  - Flexibility, modularity, exchangeability, expandability, and upgrade capability
  - Costs of instruments, consumables, and maintenance
- Medical efficacy in diagnosis, interpretation, treatment, and management
  - Improved decision making and patient outcomes
  - Critical care profile, test clusters, patient focusing, and medical indications
  - TTAT for temporal optimization and trend identification
  - Care path readiness for optimization of diagnostic–therapeutic strategies
  - Suitability for resuscitations, emergencies, peak workflow, and bursts in test volume
  - Alarms, broadcasts, and critical results notifications to physician/clinical team
  - Pattern recognition and interpretation of notable patient findings at point-of-care locations
- Hospital glucose testing – special considerations
  - Performance standards for bedside glucose testing in hospital settings should adopt LS-MAD curves and recommended error tolerance of $\leq 5\,\mathrm{mg\,dL^{-1}}$
  - POCT teams should evaluate performance and cost effectiveness in the context of tight glucose control, therapeutic decisions, and outcomes in critical care
  - Future guidelines should include LS-MAD curve pattern recognition when assessing glucose meter accuracy
  - Licensing agencies, such as the FDA, should require ISO 15197-integrated Bland–Altman and LS-MAD curve plots with highlighted discrepant values and erroneous results explained before validating POC glucose monitoring devices

CDR, clinical data repository; CIS, clinical information system; CLSI, Clinical Laboratory Standards Institute; CSF, cerebrospinal fluid; FDA, Food and Drug Administration; HIS, hospital information system; LIS, laboratory information system; LS-MAD, locally smoothed median absolute difference; POC, point of care; POCT, point-of-care testing; TTAT, therapeutic turnaround time.

Table 8 Test clusters and the critical care profile

Vital function	Diagnostic pivots (physiological indicators)
Energy	Glucose[a]
	Hemoglobin[a]
	pO_2[a]
	O_2 saturation[a]
Conduction	Potassium[a]
	Sodium[a]
	Ionized magnesium[a]
	Ionized calcium[a]
Contraction	Ionized calcium[a]
	Ionized magnesium[a]
Perfusion	Lactate[a]
Acid-base	pH[a]
	pCO_2[a]
	CO_2 content[a]
	End-tidal CO_2 tension
	Bicarbonate
Osmolality	Measured osmolality
	Calculated osmolality
Hemostasis	Hematocrit[a]
	PT[a], INR
	aPTT[a]
	ACT[a]
	D-dimer, platelet count, and function[a]
Homeostasis	Creatinine[a]
	Urea nitrogen[a]
	WBC[a]
	Chloride[a]
	Inorganic phosphate
	Cardiac injury markers[a] (e.g. myoglobin, CK-MB mass, cTnI)
Pathogen detection	Gram positive bacteria
	Gram negative bacteria
	Fungi
	Viruses (e.g. avian influenza)
	Toxins (e.g. endotoxins and exotoxins)

[a] Point-of-care whole-blood method available.
ACT, activated clotting time; aPTT, activated partial thromboplastin time; CK-MB, creatine kinase-MB isoenzyme; cTnI, cardiac troponin I; INR, international normalized ratio; PT, prothrombin time; WBC, white blood cell count.

The accuracy, precision, and linearity of whole-blood analyzers must be (i) excellent in the near-normal ranges; (ii) acceptable in the high and low extremes of measurements; and (iii) comparable for the same analytes measured on different instruments. The performance of systems for POCT is improving as technologies mature. For biosensor-based systems, performance depends on biosensor stability and reproducibility. Cartridge-based and/or single-use (unit use) systems are dependent on the quality of manufacturing for reproducible results. From a practical standpoint, use of the identical biosensor-based or cartridge-based technology in several clinical sites will facilitate consistency and, in effect, provide intramural standardization. Consistency of measurements in different sites should be demonstrated and also related to the parent laboratory as part of the proficiency-testing program. Measurements obtained with different types of systems (*in vitro*, *ex vivo*, and *in vivo*) should be consistent. As devices become more sophisticated, improved software and hardware should be incorporated for the elimination of artifacts, detection of errors, flagging of inappropriate specimens, and warning of interferences (e.g. hemolysis, bilirubin, and lipids). Small bench instruments are used frequently in satellite laboratories in operating rooms, emergency departments, and intensive care units. Inconsistent results due to instrument-specific normal reference intervals (ranges) or measurement inaccuracies become apparent as unexpected shifts that can confound accurate and swift diagnosis as, for example, the patient is transferred from the emergency department, to the operating room and, subsequently, to the intensive care unit. Significant progress has been made with bar coding and menu-driven touch screens. However, the integration of information at the POC and interlinking of satellite sites are not yet developed adequately. Instruments should be interfaced with computerized laboratory information systems (LISs) or networks. Bidirectional interfacing and electronic archiving are important. Interfacing should be flawless with prompt access to the LIS and the hospital information system (HIS). Systems should conform to emerging standards for the connectivity of POC devices.

Instruments should have the potential for integration with physiological monitoring systems used in intensive care. Data management systems to integrate biochemical and physiological data are invaluable and should be anticipated at the time of instrument selection. Cabling from several bedside instruments and critical care monitors should be consolidated, or patient results communicated to a base station by wireless communication and telemetry. Notification of critical patient results is essential. For example, the risk of miscommunication of actionable or critical results during a fast-paced patient resuscitation is great. The data stream of results flows so quickly that assimilation into the patient record, a legal necessity, often lags behind real-time care and can impair the clinical timeliness of whole-blood tests. Conventional local and wide area networks, fiber-optics networks, electronic mail, facsimile machines, two-way radios, beepers, and cellular phones can help to facilitate communication as needed. This situation calls for the increasing use of robotics, remote review, artificial intelligence, and intelligent decision systems.[70–72]

Several publications are available that explain how to qualify new devices or new tests for clinical service, such as publications from the CLSI.[72] This CLSI document covers experimental design, data examination, linear regression, bias, results interpretation, and performance

criteria. The quality division in each institution should design its own protocols for the qualification of new methods of POCT. For example, a designated reference instrument can be moved on-site (e.g. on a mobile cart) for side-by-side anaerobic split-sample comparisons. Transporting and then analyzing whole-blood samples for comparison studies performed at distant sites may introduce preanalytical errors and is inadvisable. Individual instrument histories, tracking records, and comprehensive quality assurance are essential. Performance of operators can be evaluated using control materials, blind samples, and proficiency testing. Instrument performance can be assessed through quality control, proficiency testing, and pattern-recognition techniques. New approaches to quality validation are needed for single-use (unit use) cartridges and test strips and for *ex vivo* and *in vivo* systems. External and internal electronic checks are being accepted by accreditation agencies but must be validated. Some manufacturers and hospitals have developed on-site programs, videos, and teaching aids to educate operators and explain new approaches to quality management and method comparison. Note that education and training programs must satisfy federal, state, and professional accreditation requirements. A quality alliance of laboratory personnel, manufacturers, and regulators is essential to transform laws, rules, and inspections into an integrated quality-based system.

3 CRITICAL-EMERGENCY-DISASTER CARE

The Southeast Asian Tsunami of 2004 and Hurricane Katrina in 2005 revealed the lack of disaster medical preparedness worldwide. POCT was numerous and the disaster response was massive, however, as the results showed, this was quite insufficient. During these two recent disasters, hospitals, roadways, and communications were quickly compromised. POCT and other medical instruments no longer function under these adverse conditions. Ultimately, these recent disasters have shown the current weakness of POCT, but revealed the potential of POCT to play a significant role to augment the damaged, destroyed or overwhelmed healthcare infrastructure.

POC in Thailand and the Asian Tsunami. On Phi Phi Island in Thailand following the tsunami, diagnostic testing was limited to glucose meters, spun hematocrit, and urine dipsticks for protein and glucose. In the costal areas of Thailand, frequent cases of aspiration were assessed for severity by POC pulse oximetry. No quantitative cardiac biomarker testing was available.[47]

POC in New Orleans and Hurricane Katrina. In New Orleans, following Hurricane Katrina, the US disaster response was massive, but inadequate to deal with the loss of 11 Louisiana hospitals.[47] The US military, National Disaster Medical System (NDMS), and Disaster Medical Assistant Teams (DMAT) from across the country responded with mobile hospitals equipped with limited POCT instruments. Military POC instruments included handheld or portable whole-blood analyzers, ABO blood typing, glucose meters, cardiac biomarkers, pulse oximeters, and drugs of abuse tests. POCT for DMATs were limited to handheld whole-blood analyzers, pulse oximeters, and glucose meters. Both the military and DMATs are the quintessential platforms to deploy POCT for any current or future disaster response.

In both disasters, environmental extremes hampered diagnostic medical devices. Flooding, no clean water, 32.22–37.78 °C temperature, 100% humidity, power loss, and destruction of cell and landline phone systems crippled the medical infrastructure.[47] This beckons the question, if POCT can provide results under these conditions. A study by Sumner et al. showed common POC instruments including glucose meters and a handheld whole-blood analyzer to provide erroneous results under extreme conditions. In some cases, instruments failed to operate.[48] GMSs showed sensitivity to high and low temperatures. The test cartridges for handheld blood gas analyzers that are carried by DMATs are affected by high and low temperatures (Figure 10).[48] Some suggest that these instruments should be operated in close proximity to portable air conditioning units.[73]

There is a clear need for POCT instruments for field medicine, and disaster response. Disaster response POCT should be designed with DMAT use in mind and accompanied by educational programs.[73] POC instruments and reagents should be field robust (e.g. vibration, humidity, temperature, salinity, barometric pressure, and exposure). Instruments should be standardized for first responders and DMATs with interchangeability of equipment and common training. Connectivity of instruments is also essential to provide wireless networking capabilities during disaster response management (e.g. patient tracking) and potential integration into telemedicine systems.[74] Health care personnel must be aware of the potential for aberrant results when current POC devices are stressed beyond their normal operating parameters.

4 TEST CLUSTERS (CRITICAL CARE PROFILE) AND MEDICAL INDICATIONS

The innovation of a critical care profile (Table 8) further minimized the response time for whole-blood analyses.[2,70,75–77] Fast TTAT of 2–5 min was necessary

Figure 10 Effects of heating and cooling of test cartridges on pO_2 results obtained with a handheld blood gas analyzer. This figure shows the mean pO_2 paired-differences between heated (40 °C) or cooled (2 °C) test cartridges and control (21 °C). Cartridges were thermally stressed for 12–72 h.

during liver transplantation.[21] Transplant procedures (and massive transfusions) demonstrated the significance of ionized calcium, the time value of diagnostic test results, and the efficacy of the critical care profile. Historically, an important milestone occurred when the critical care profile combined whole-blood ionized calcium (Ca^{2+}) and electrolytes (K^+, Na^+, and Cl^-) with blood gases (pO_2 and pCO_2), pH, and hematocrit on one instrument platform. Now biosensor-based whole-blood measurements in critical care clusters include ionized magnesium, glucose, lactate, urea nitrogen, creatinine, and CO_2 content.[9] Several other medically important critical care tests, combined strategies, and novel approaches are available, or soon will be. User-definable and patient-focused test clusters provide valuable indicators of vital functions, such as those listed in Table 9.

Organ injury markers, such as markers of myocardial injury, and hemostasis–thrombolysis tests (see below), are important recent additions to the POC armamentarium. Each test added provides the physician with extra flexibility and improves the cluster efficiency significantly. In the future, the number and variety of whole-blood tests available at the point of care will expand dramatically as microfabrication/nanofabrication advance, chip-based technologies mature, and the critical care marketplace allows. Availability of a wide range of diagnostic pivots in appropriately selected test clusters expands the spectrum of clinical indications for POCT. These indications now are relatively broad and include critical conditions such as cardiopulmonary arrest, endocrine crises (e.g. diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic diabetes with coma), pulmonary problems (adult respiratory distress syndrome, ARDS), pulmonary embolism, and respiratory failure), hemorrhage (e.g. acute gastrointestinal or postsurgical bleeding), seizures, and numerous others. Hence, vital functions and their diagnostic pivots form the criteria for the selection of patient-focused test clusters and critical care profiles.

Table 9 summarizes the indications, applications, and limitations of POC tests for hemostasis, thrombolysis, and thrombosis. POC tests such as hemoglobin, hematocrit, and white blood cell count (WBC) are used in several clinical domains. Other tests in this area have relatively specific indications. Patient-focused testing for PT to monitor the status of ambulatory patients on coumadin therapy has been used effectively. In critical care, activated partial thromboplastin time (aPTT) and activated clotting time (ACT), historically an early on-site test used in the operating room, are frequently performed at the POC to monitor heparin anticoagulation, protamine neutralization, and the patient's status before, during, and following cardiac surgery, invasive procedures (such as coronary catheterization), and dialysis. PT and aPTT are valuable indicators in trauma patients who have head injury associated with unconsciousness or focal neurologic deficit, and therefore delayed intracranial hemorrhage is suspected.

This area is one of critical need and rapid expansion. Established large companies have recently invested heavily in research and development. Several new methods that assess platelet function, thrombosis, and thrombolysis are under development, in clinical trials, or moving to the POC. Some tests will be used to predict adverse responses to thrombolytics. Tests for clotting (e.g. TpP, thrombosis precursor protein), if clinically validated, may be useful in clusters with metabolite tests (e.g. lactate) to detect coronary artery thrombosis. These test clusters could complement cardiac injury markers, such as CK-MB, myoglobin, and cTnI, an important "triplet" cluster. Clearly, tying together key clusters of tests is a valuable benefit of POCT and represents the

Table 9 Hemostasis, thrombolysis, and thrombosis tests for the point of care

Diagnostic pivot(s)	Indications, applications, and limitations
ACT (ACT-Plus[a,b,c])	Surgery, invasive procedures, hemodialysis, arterio- and venovenous dialysis
ACT ≥ target threshold (e.g. 400 s)	CPB, PTCA (high heparin levels, strong contact activator in reagents)
ACT ≤ target threshold	ECMO, stents, catheter sheath removal, pharmacological agents[d] (low heparin levels, moderate activator)
aPTT	Heparin anticoagulation monitoring–indications listed above (low heparin levels), intrinsic coagulation screening and monitoring treatment (e.g. hemophilia A)
Clot signature analysis (TEG,[e,c] others[f]	Transplantation, CPB, protracted surgery
D-dimer (XL-FDP)	Deep vein thrombosis, PE, DIC, preeclampsia, reactive fibrinolysis (qualitative point-of-care, quantitative immunoassay devices)
Fibrinogen	Preanalytical processing required; under development for whole blood at point of care[g]; thrombolytic therapy; 1° (congenital) and 2° (acquired consumptive coagulopathy-DIC, liver disease) hypofibrinogenemia; after surgery, ECMO
Heparin dose-response	Improved precision in monitoring anticoagulation and relative insensitivity to hemodilution and hypothermia; various heparin management systems/panels[h]
Platelet count and function	Transfusion therapy, drug effects, screening for acquired and congenital platelet problems
PT (INR)	Coumadin anticoagulation monitoring, extrinsic coagulation screening – bedside, clinics, physician office laboratory, home monitoring, other settings
Thrombin time (HNTT,[i,b,c] HiTT[i,b,c])	Indirect fibrinogen function, heparin therapy, DIC status; rarely used at the bedside
Thrombolysis (fibrinolysis)	Determining or predicting response to thrombolytics, tracking lytic state; tests for thrombolytics (e.g. streptokinase, TPA, urokinase) and lysis onset time (LOT[g,c]) are under development or in clinical trials
Thrombosis (TpP[j,c])	Suggested in acute myocardial infarction, PE, stroke; clinical validation and point-of-care test pending

CPB, cardiopulmonary bypass surgery; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; PE, pulmonary embolism; PTCA, percutaneous transluminal coronary angioplasty; TPA, tissue plasminogen activator; XL-FDP, cross-linked fibrin degradation products.

[a] Used in cases of hypothermia, hemodilution, and antifibrinolytic drugs in CPB and cardiac catheterization.

[b] International Technidyne Corporation, Edison, NJ.

[c] Proprietary.

[d] Thrombin inhibitors and platelet IIa–IIIb blockers.

[e] TEG, thromboelastography (Haemoscope, Morton Grove, IL).

[f] Sonoclot (Sienco, Denver, CO) and Xylum (Scarsdale, NY).

[g] Cardiovascular Diagnostics Incorporated, Raleigh, NC.

[h] 1, Heparin Management Test;[g] 2, Hepcon Hemostasis Management System (Medtronic, Parker, CO); 3, RxDx Anticoagulation Management System.[b]

[i] HNTT, fibrinogen function in the presence of heparin; HiTT, CPB, high heparin levels and antifibrinolytics.

[j] TpP, thrombosis precursor protein (American Biogenetic Sciences, Copiague, NY).

precursor of multimarker risk indexing for specific disease and diagnoses.

For coagulation testing, special preanalytical problems may arise due to specimen acquisition and sample handling. To avoid preanalytical problems, blood samples obtained from existing lines or venipunctures must be collected carefully. Clotting and hemolysis, which can also affect electrolyte results (e.g. K^+), must be avoided. In fact, an ideal POC device would not only detect but also flag specimen problems and disallow inaccurate results. Proper sample collection requires training and experience. Preanalytical errors occur, for example, if there are delays, since blood begins clotting immediately after removal from the body, or when a citrated tube is used for anticoagulation but the tube is not properly filled with blood and the sample is not mixed adequately. Additional problems arise in the elderly, who may have poor peripheral circulation, and in premature infants, who have small blood volume and do not tolerate excessive numbers of heelsticks. Nonanticoagulated whole blood obtained by fingerstick can create artifacts in coagulation tests, change over time due to instability, and present biohazards for the operator. Clinicians must be aware of the normal and therapeutic ranges for POC test results used in clinical decisions. Therefore, it is vital to carefully evaluate (i) the preanalytical steps required; (ii) whether the blood sample is anticoagulated or not; (iii) the POC test method used; and (iv) the relationship to results obtained with either whole-blood or plasma-based methods in the parent laboratory (main laboratory) when implementing POC tests for hemostasis, thrombosis, and thrombolysis in individual critical care settings.

5 ACCURACY ASSESSMENT

Numerous methods are available to determine the accuracy of POC instruments. These include national and international standards (e.g. CLSI and ISO), as well as pattern recognition and new statistical methods to determine if POC devices are comparable to reference instruments. Pattern-recognition methods, such as mountain plots, scatter plots, median absolute difference (AD) plots, and Bland–Altman plots, can be used. Illustrative methods such as the Bland–Altman plot may be coupled to standards like the CLSI and International Organization for Standardization (ISO) criteria.[78,79] For statistical methods, examples include the Student's *t*-test, analysis of variance (ANOVA), and least squares linear regression. This section also describes the most recent approach, locally smoothed median AD curves.

5.1 Pattern-recognition Methods

These methods allow for quick determination of biases, trends, and errors. The mountain plot, also called an *empirical cumulative distribution plot*, allows for easy identification of the central 95% of the data and provides clearer differentiation of two distributions (e.g. GMS versus reference).[79] It is generated by computing the percentile for each ranked difference between the device versus the reference. The plot shows the median bias between the two methods, while the tails of the plot show the propensity for the new method to deviate from the comparison method.

POC device versus reference instrument scatter plots are commonly used for linear regression. In glucose monitoring accuracy assessment, an error grid can be applied to the regression plot. Error grids such as the Clarke Error Grid divides a scatter plot (glucose meter versus reference) into five zones (A, B, C, D, and E).[80] Data points falling into zones A and B are considered acceptable, while data falling into zone C indicate that the glucose meter's results may prompt unnecessary corrections. Zone D and E represent dangerous failure to detect a glucose level or results causing erroneous treatment, respectively. More recently, there has been the introduction of the continuous glucose error grid that allows a user to evaluate the accuracy of continuous glucose monitors. The five zones are retained; however, the shape of the error grid allows the investigator to also evaluate the glucose rate (e.g. blood glucose as a function of time).[81]

Median AD curves provide a nonparametric method at illustrating performance data. Medians are calculated from the dataset for each reference value. Data points are plotted on a median AD (y axis) versus reference (x axis) curve. The curve is not biased by extreme values due to its reliance on medians, and does not require a normally distributed data set.

The modified Bland–Altman plot is a bias plot (bias versus reference).[82] Bias (POC instrument–Reference) is on the y axis, and the x axis is the reference. This method is useful in that it shows bias, trends, and errors. When coupled to standards (e.g. CLSI, ISO, American Diabetes Association), these plots serve to identify if an instrument meets the acceptance criteria. For example, a recent draft FDA guideline proposes the use of the ISO 15197 criteria integrated with the modified Bland–Altman plot for glucose meter accuracy assessment.[83] In situations where a reference is not available, the bias can be calculated between two instruments (y value) and compared against the average value between the instruments (x value).

5.2 Locally Smoothed Median Absolute Difference Curves

Locally smoothed median absolute difference (LS-MAD) is a nonparametric method of transforming discrete points on an $x-y$ plane into a continuous curve that helps reveal underlying patterns.[82] This method provides a representation of instrument performance versus a reference through the entire range of testing. The curve contains points (x, y) where y is the median of the values, y^*, for all points (x^*, y^*) in the range $[x-h] \leq y^* \leq [x+h]$. The bandwidth, h, controls the degree of smoothing.

Values are calculated from integer values only. Each value at point x is the median of the AD of all paired instrument and reference measurements where the reference result is within the specified distance, the bandwidth of x. The discrete median points are then connected to generate a single continuous curve. Ideally, LS-MAD curves should be as close as possible to the x axis (low MAD), and be relatively flat.

Figure 11 illustrates the LS-MAD methodology applied to glucose meter versus a reference analysis. ADs are calculated, and a median AD is generated at each reference value based on a bandwidth of 15 mg dL^{-1}. This bandwidth, h, of 15 mg dL^{-1}, where $2h = 30$ mg dL^{-1}, was selected to correspond to a TGC interval of 80–110 mg dL^{-1}.

Improved performance is achievable by correcting for confounding factors such as hematocrit, pO_2, and the effects of drug-oxidizing drugs. The StatStrip GMS (Nova Biomedical, Waltham, MA) is one such example. Recent multicenter evaluations demonstrate the new StatStrip GMS, a sample size of 2767 paired observations having higher accuracy and precision when compared to competing systems. The LS-MAD curve for the StatStrip remained below the 5 mg dL^{-1} tolerance from 35 to 179 mg dL^{-1} (Figure 12a).[84] Figure 12(b) and

Figure 11 The approach to generating and interpreting an LS-MAD curve is illustrated from left to right in three separate sequential frames. Frame A illustrates the calculation of the LS-MAD y value (y^*) at the point x (see the crosshair). The LS-MAD curve (shadowed) smoothes the variation in the underlying absolute difference (AD) scatterplot; y^* represents the median of the ADs (AD1, AD2, through ADn) for points between $x - h$ and $x + h$, where h is the bandwidth (15 mg dL^{-1}). Frame B shows that twice ($2h$) the bandwidth (h) matches the span of the TGC interval (30 mg dL^{-1}) that we selected on the basis of its efficacy for improving outcomes (15–17). Frame C emphasizes that the LS-MAD curve will instantly reveal regions, such as the high glucose range, where bedside testing performance needs to be improved significantly.

(c) illustrate (e.g. modified Bland–Altman plot and least squares linear regression) methods. We defined erroneous values as values falling outside of ISO 15197 tolerances. Competing meters, which did not correct for confounding factors, performed poorly under LS-MAD analysis and exhibited a high frequency of erroneous values.[85]

5.3 Discrepant Values

Discrepant values represent errors that could significantly impact the effectiveness of TGC protocols.[54] Two classes of discrepant values exist, Class I and Class II. Class I discrepancies are pairs with reference values below the lower TGC limit (e.g. <80 mg dL^{-1}) and GMS values above the high TGC limit (e.g. >110 mg dL^{-1}). Class II discrepancies are pairs with reference values above the high TGC limit and GMS values below the lower TGC limit. Class I discrepancies represent the most serious type of error since they can lead to dangerous clinical decisions and, in the context of TGC, hypoglycemia. Conversely, class II discrepancies are less serious since they could only lead to aggravation of hyperglycemia. The concept of discrepant values can be applied to any POC analyte for which simpler diagnostic-therapeutic decision making is made at the bedside.

5.4 Statistical Methods

Statistical tests can provide p values or correlation coefficients. The most common statistical test is the Student's t-test.[37] Three kinds of t-test's exist: one sample, two sample, and the t-test for paired differences. For the purposes of comparing a GMS versus a reference analyzer, we must use the Student's t-test for paired differences since we are comparing the same blood sample. The Student's t-test for paired differences assumes that the samples are not independent (e.g. using the same blood samples), and the data is normally distributed. ANOVA is another statistical method, which compares the differences of three or more groups of data. This is very useful for comparing variations between different test strip lots. Both the Student's t-test and ANOVA generates a p value where $p \leq 0.05$ is usually considered statistically significant.[86]

Ordinary least squares linear regression, or commonly referred to as *linear regression*, generates a best-fit line onto a scatter plot (POC instrument versus reference analyzer).[37] The correlation coefficient (r), coefficient of determination (r^2), and equation of the line are generated on this plot. The r^2 value is commonly used, with r^2 ranging from 0 to 1, where 0 indicates a nonlinear relationship, and 1 being a perfect fit. Manufactures strive to attain a very high r^2 value since it indicates high correlation between GMS and the reference. However, it must be noted that least squares linear regression is very susceptible to the weighting effects of data points at extreme values. For example, if a single value at a high reference range falls on the regression line, it may provide a high r^2 value. Removal of this data point may then reveal the less than satisfactory nature of data set. Therefore, investigators must be aware of the potential for data to have poor agreement but still produce relatively high correlations.

Figure 12 (a) Locally smoothed median absolute difference curve ($n = 2767$ paired observations). This plot shows an LS-MAD curve and the 95% confidence intervals for a glucose meter that automatically adjusts for hematocrit effects when compared to a laboratory analyzer (120 different analyzers). The TGC range (80–110 mg dL^{-1}) is shown in gray, and the arrow identifies where the LS-MAD curve breaks out of the 5 mg dL^{-1} error tolerance at a reference value of 179 mg dL^{-1}. (b) Least squared linear regression plot ($n = 2767$). This plot shows a least squares linear regression plot. $r^2 = 0.995$ and $y = 1.012x - 0.021$. (c) Modified Bland–Altman ISO 15197 integrated plot ($n = 2767$). The ISO criteria requires that 95% of data points less than 75 mg dL^{-1} have a bias of no more than ±15 mg dL^{-1}, while for 95% of data points equal or greater than 75 mg dL^{-1}, the bias must fall within 20% of reference values. When compared to 120 different laboratory analyzers, this glucose meter has 99.15% (581/586) of data points falling within tolerances for reference values <75 mg dL^{-1} and 99.81% (2177/2181) of data points ≥75 mg dL^{-1} falling within tolerances. The mean bias was −2.19 mg dL^{-1} (SD ±9.61, $P < 0.001$).

5.5 Future Concerns

There is a clear need for POC instruments, which account for confounding factors. POC instruments affected by confounding factors may generate erroneous results and discrepant values that lead to adverse treatment decisions, a key concern in settings such as TGC for critically ill patients.[54] Recently, there has been a substantial effort

to account for confounding factors such as hematocrit. Results have shown improved performance over clinically significant ranges. As biosensor technology continues to improve, future instruments should be evaluated on the basis of more stringent performance criteria and unbiased statistical methods to determine accuracy. Additionally, POCT accuracy should be based on absolute global standards, rather than on relative performance and equivalent methods.

6 MONITORING PERFORMANCE

6.1 Total Quality Principle for Point-of-care Testing

Complex critical care settings warrant careful consideration of strategies for enhancing performance. Good strategies transcend statutory requirements. Therefore, the goal of this section is to introduce, as a guiding concept, the *total quality principle* for POCT, and then to discuss the general approach to accreditation, to outline regulatory requirements for POCT programs, to describe how to enhance performance by avoiding common inspection pitfalls and by improving training and education programs, and to identify the role of the clinical laboratory in supporting critical care testing. It may be noted that regulatory requirements are perpetually changing and, hopefully, continuously improving. Accreditation agencies can be contacted via their home pages on the World Wide Web, or directly for the latest information. For general guidelines that reflect the standard of care for POCT, one may refer to Kost.[1]

The Clinical Laboratory Improvement Amendments of 1988[87] (CLIA'88) imposed graded regulatory requirements based on the level of test complexity (the "complexity model") rather than on the location of diagnostic testing, the so-called site neutrality principle. Test categories include waived (e.g. nonautomated spun hematocrit, gastric and fecal occult blood tests, and pH in body fluids such as amniotic fluid and gastric aspirates), moderate complexity (e.g. Ca^{2+}, blood gases, microscopy, and accurate and precise technology), and high complexity. The moderate complexity category includes most diagnostic tests. For a comprehensive discussion of CLIA'88 test categories, personnel descriptions, and regulatory requirements for decentralized testing, please see the summary[88] by authorities, who state, "to know CLIA is to know the other regulations – all of the other regulations are based on CLIA'88".[24] The World Wide Web home page of the FDA updates CLIA-waived tests (see Appendix). The home page of the American Association for Clinical Chemistry offers CLIA information ("CLIANET"). CLIA'88 established the requirement for site neutrality and, in doing so, defined a common denominator of the regulatory process. Revised CLIA rules are anticipated, but the principle of site neutrality is likely to remain a permanent feature in the future.

On the basis of the concept of site neutrality, then, the *total quality principle* for POCT means empowering professionals who proactively integrate quality control, quality monitors, and proficiency testing into one patient-focused package that meets customer needs *irrespective of where the diagnostic testing is performed*. The overall goal is to improve the integrated outcomes of the diagnostic testing process. The practical strategy is total quality management. As part of the total quality management, each institution must design its own performance enhancement program. Performance is enhanced by establishing quality monitors, perpetually assessing trends, and continuously devising new ways to improve quality. Continuous quality improvement is an important objective that all accreditation agencies promote. Another important objective that accreditation agencies share is the demonstration of satisfactory proficiency-testing results (see below). Proficiency testing objectively determines the overall quality and integrity of diagnostic testing services.

6.2 Accreditation and Regulation

6.2.1 Joint Commission on Accreditation of Healthcare Organizations

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) is a voluntary accreditation agency. The Health Care Financing Administration (HCFA) has determined that JCAHO accreditation standards are equivalent to or exceed those of CLIA'88. Laboratories accredited by JCAHO are deemed to have met CLIA'88 requirements. Therefore, it is important to understand JCAHO requirements for POCT.[89–92] In contrast to the lack of regulatory requirements for tests waived under CLIA'88, JCAHO has several relatively stringent requirements. These requirements include, for example, definition of medical use, identification of operators and supervisors, written procedures (including specimen collection and preservation, equipment performance evaluation, test performance, instrument calibration, and quality control and remedial actions), quality control checks that meet at least the manufacturer's minimum recommendations, and long-term maintenance of patient testing and quality control records. Training and continued competence must be documented by means of split-sample unknowns, observation of technique, or acceptable performance on quality control checks. For both waived and moderately complex tests, it is particularly important to document who is responsible for testing

and what measures are taken when correcting quality control failures or other problems.

Under CLIA'88, most POC tests used in the operating room and intensive care unit fall into the moderate complexity category. Like CLIA'88, for these tests, JCAHO requires compliance with manufacturers' instructions, a procedure manual, periodic calibrations, written control procedures, two-level quality control checks each testing day (or more frequently depending on the type of test), documented remedial actions, and two-year record keeping. JCAHO currently accepts electronic checks, but recommends that liquid controls also be run periodically to help confirm electronic control results. JCAHO also demands evidence that the performance of the method is verified prior to use at the POC. This evidence includes the demonstration and documentation of accuracy (through comparison of split samples, analysis of controls, or proficiency testing), precision (through replicate analysis of patient specimens or of control materials from one lot), reference intervals suitable for the patient population, and validation of high and low values (through linearity studies or comparisons to other instruments). JCAHO requires participation in a proficiency-testing program (except for waived tests) and demonstration of the consistency (correlation) of test results obtained at different POC sites, whether or not the sites participate directly in the proficiency-testing surveys of the parent and/or main laboratory. However, only one methodology or analyzer per analyte (under each CLIA certificate) needs be enrolled in proficiency testing. Corrective actions for proficiency-testing failures must be taken promptly and carefully documented.

For hospitals lacking a consolidated POCT program, vulnerability occurs where quality monitoring activities are not integrated. That is, during inspections, JCAHO may require documentation showing that the loop of total quality management (consisting of instruments, quality monitors, and patient test results) was closed during the same time interval when the audited test results were used in patient management. Typically, POCT sites are widely distributed, and often instrument interfaces to hospital and LISs are limited. Therefore, seamless linkage of patient test results and quality monitor results to the electronic medical record is a major advantage when satisfying JCAHO requests for these audit trails. Institutions that have implemented electronic patient record systems and instrument interfacing are well positioned to track and manage the quality of POCT. JCAHO recently required hospitals to implement one or more performance measurement systems that collect data and report results to JCAHO quarterly, two clinical measures in the form of metrics that relate to more than 20% of the hospital's patient population, and peer group comparisons for both the clinical laboratory and the hospital as a whole.

6.2.2 *College of American Pathologists*

Like JCAHO, the College of American Pathologists (CAP) is a voluntary accreditation agency. The CAP laboratory accreditation program has also received deemed status from HCFA. Additionally, JCAHO will accept CAP accreditation in lieu of a detailed laboratory inspection. The standards of the CAP laboratory accreditation program are the most demanding of any of the accreditation agencies.[93] CAP treats all tests, including those performed at the POC, as highly complex under CLIA'88. A physician or doctoral scientist must be responsible for POCT. When CAP inspects and accredits POCT, bundling it with the clinical laboratory under one CLIA'88 registration number (certificate) and one director is most efficient. Consolidation is also advantageous since fewer directors, licenses, and inspections lower fees and reduce the overheads for POCT programs. The reader is encouraged to consult with CAP directly for details of general requirements and to review the following three checklists: (i) the limited services checklist (no. 25) that evaluates satellite and stat laboratories; (ii) the blood gas laboratory checklist (no. 26) that evaluates sites performing blood gas and whole-blood analyte tests; and (iii) the POCT checklist (no. 30) that evaluates testing performed with handheld or portable instruments that are carried to the bedside and do not require permanent dedicated space. Checklist no. 30, which previously was titled *alternate site testing,* covers only a subset of POCT services. Hence, the other checklists must also be reviewed.

Notable features of the CAP POCT checklist (no. 30) include (i) the strict verification of performance (e.g. accuracy, precision, analytical sensitivity and specificity, reportable range, reference interval, and calibration verification and/or linearity); (ii) a thorough continuous quality improvement program, with quality control required even for tests waived under CLIA'88; (iii) the option to use electronic quality control, that is, ''a scientifically acceptable alternative control system . . . that controls the entire analytic process'' (question 30.0550); and (iv) documented weekly review of quality control by a technical supervisor, plus secondary monthly review by a director or designee; and (v) participation in the CAP proficiency-testing program, processing of survey samples ''in a similar manner as patient specimens'', and analysis by personnel who routinely test patient samples (Q30.0325).

There must be defined criteria for correlating unexpected test results with other clinical findings to validate results (Q30.0370). There is also a question intended

"to minimize unnecessarily large blood draw volume" (Q30.0435) and others (Q30.0455, Q30.0460) to ensure that critical limits are established, critical results are notified, and notifications are documented, unless test results are given directly to the physician. Near-patient testing of blood gases and whole-blood analytes in satellite laboratories is covered by checklist no. 26, if the near-patient sites have separate administration and directorship but are inspected by CAP in parallel with the main laboratory. Near-patient laboratories are common in critical care.[75,76] Therefore, near-patient and POCT should be carefully coordinated and integrated in order to streamline accreditation, improve cost effectiveness, enhance performance, and benefit patient care.

6.3 Performance Enhancement and Continuous Quality Improvement

6.3.1 Avoiding Common Pitfalls of Accreditation Inspections

Common inspection deficiencies under CLIA'88 include (i) weak definition of responsibilities, poor documentation of competency, and ineffective education and training programs; (ii) noncompliance with manufacturers' directions and lack of procedure manuals; (iii) inadequate quality control, quality assurance, proficiency testing, and total quality assessment; and (iv) absence of periodic calibrations and verification of the accuracy of analytes omitted from proficiency testing. During JCAHO inspections, commonly encountered deficiencies include (i) absence of test and control records for methods in the CLIA'88 waived category; (ii) lack of review and remedial actions for proficiency-testing problems with moderately and highly complex tests; (iii) inadequate surveillance of test results and quality monitors; (iv) insufficient compliance with laboratory safety requirements; and (v) various problems with fulfillment in technical areas such as analytical evaluation, preventative maintenance, and adequate space. Note that United States Occupational Safety and Health Administration (USOSHA) requirements (e.g. universal precautions) must be met. Also, always consult the manufacturer to check that the device was cleared by the FDA for POCT and to determine the test complexity category.

CAP checklists are "tools for inspectors and directors to use in evaluating whether or not the laboratory is meeting the standards for laboratory accreditation".[93] On the basis of the CAP POCT checklist (no. 30), common inspection deficiencies encountered are associated with (i) reviewing results (supervisor), protocols, and quality control; (ii) pursuing corrections for quality control results out of tolerance limits; (iii) performing positive and negative controls for qualitative tests; (iv) documenting the quality control program and reference intervals; (v) detecting errors and unusual or unexpected test results; (vi) periodically verifying linearity; (vii) labeling reagents; and (viii) participating in proficiency testing. Deficiencies also arise when proficiency testing is not done by testing personnel or when no corrective actions are taken following proficiency-testing failures.

Analysis of these common CLIA'88, JCAHO, and CAP inspection deficiencies reveals the importance of the total quality principle and continuous quality improvement for POCT. Many of the common pitfalls of accreditation inspections can be avoided through adequate preparation, ongoing supervision, and common sense. For example, testing controls, recording results, remedying problems, and reviewing performance are essential to avoid adverse events associated with the diagnostic testing process, irrespective of where the testing is performed. Proficiency testing is designed to reflect the overall quality of the POCT program and to improve it. Proficiency testing also can be used to assess personnel competency, even, as suggested by JCAHO, for tests waived from this requirement under CLIA'88. Total quality management helps assure that the integrated outcomes of the quality monitoring process reflect the level of performance expected when test results are actually used in clinical decisions.

Hospitals can benefit medically and economically from consolidating total quality management in the hands of one unified group of interdisciplinary "hybrid" personnel.[3,72] The expertise of this multidisciplinary team should span the spectrum from intensive care to laboratory medicine. Laboratorians are professionally trained and experienced in the total quality principle. Their scope is the entire health care system. They can be vested with both authority and responsibility for the design of the quality assurance and proficiency-testing program. Laboratorians can perform important tasks, such as evaluating technology, correlating methods, defining normal ranges, writing protocols, managing instruments, coordinating supplies, providing backup, addressing problems, improving safety, demonstrating technique, and integrating services. They are skilled in computerized informatics for quality control and patient test results tracking. They also can oversee and document the training, education, and certification of clinicians who perform POCT. When part of the performance enhancement team, experience has shown that laboratorians who bridge disciplines and manage quality programs work well with clinicians and accreditation agencies to achieve and, typically, surpass the level of performance required for all types of POCT.

6.3.2 Clinical Laboratory Standards Institute Guidelines

CLSI guidelines emphasize important program objectives, such as performance of instrument maintenance and function checks, patient test performance, recording and reporting of patient results, assessment of problem-solving skills, verification of knowledge by examination, and use of operator proficiency in personnel evaluations.[93,94] It is important that specimen acquisition be performed safely with positive patient identification. Sample transfer should be performed properly to avoid preanalytical errors. Quality control should be rotated among operators who should document quality control results and corrections following quality control failures. Authority to qualify personnel, assure that quality control standards are maintained, and prohibit inappropriate use of POC instruments is pivotal to successful performance. Thus, CLSI guidelines call for a thorough understanding of the principles and practice of POCT. The reader is encouraged to contact the CLSI directly for emerging guidelines that are being developed, undergoing revisions, or pending approval; please send e-mail (exoffice@CLSI.org) or use the CLSI World Wide Web home page (http://www.CLSI.org).

7 STRATEGIES FOR OPTIMIZATION OF POINT-OF-CARE TESTING

Table 10 outlines general strategies to optimize laboratory diagnostic support for critical care and other areas. These include establishing a critical care profile, selecting instruments designed for critical care, minimizing response time, and targeting critical opportunities.

Table 10 Strategies to optimize POCT

Establish critical care/patient-focused care profiles
• Fulfill clinical objectives by selecting key tests
• Combine tests in clusters to improve efficiency
• Monitor vital functions using test clusters
Select instruments designed for POCT
• Use direct whole-blood measurement
• Eliminate centrifugation
• Conserve blood
Minimize response time and maximize connectivity
• Create patient proximity
• Reduce specimen transit time
• Report results immediately
Target critical opportunities
• Identify surrogates of sublethal and lethal events
• Track quantitative metrics
• Focus on medical and economic outcomes

A critical care profile should fulfill clinical objectives, combine tests in clusters to improve efficiency, and monitor vital functions. A technological and clinical hurdle for POC instruments is limited flexibility in the selection of tests or test clusters. POC devices are progressing through a developmental stage limited by test subsets. That is, the subsets are not necessarily patient focused. Test menus are limited relative to actual needs in critical care medicine and other disciplines. Current technologies allow the purchase of a defined test menu on a transportable or portable platform, the use of personal testing devices (PTDs) with a few tests or fixed-menu cartridges, or for remote review systems, the selection of analytes in a ''minimenu'' based on limited methods available at a near-patient workstation (automated testing machine (ATM), or automated testing instrument (ATI)). Storage of excess expiration-dated electrodes, cartridges, or reagents that may go to waste should be avoided. Ideally, a physician should be able to select individual tests or clusters of tests needed at the time of decision making, choose from a menu of at least 30–50 analytes, and pay only for those tests actually used.

Given current technological limits, rapid device diffusion, and significant fiscal constraints, it is important to use direct whole-blood measurement, to eliminate centrifugation and other preanalytical processing steps, and to conserve blood in order to eliminate unnecessary blood transfusions and their hidden and downstream risks. Handheld devices typically require several preanalytical and postanalytical processing steps. Extra labor and supplies costs cannot be ignored. If assessed objectively from a cost-accounting perspective, numerous small processing steps performed by individual caregivers add up to large financial burdens for the integrated health system. In addition, biohazard risks must be taken into consideration. Since blood specimens are handled manually and often without containment, serious biohazard exposures can occur. Staff members are at risk of infection. Critically ill patients may be in isolation, laminar flow, or other special environments that call for biohazard containment during diagnostic testing procedures. All patients must be carefully protected from acquiring hospital-borne pathogens. Instruments with carefully designed biohazards containment occupy a position of high priority in critical care.

To minimize response time, it is necessary to either create patient proximity, that is, perform testing at or near the site of patient care, or to reduce specimen transit time to the main laboratory, and in either case, to report results immediately. Historically, the LIS solved several problems associated with slow reporting of results by reducing or eliminating delays during the postanalytical phase through computerized processing, telecommunications, and networks. Hospitals

are building on this progress by installing infrared, wireless, and other communication modalities, either in conjunction with the LIS (e.g. "virtual" laboratory handheld digital assistants) or as part of other point-of-service systems (e.g. nursing, respiratory, or inventory wireless touchpads). POCT appeared later historically than computerized information transmission.

7.1 Point-of-care Connectivity

Connectivity is the ability to reliably transfer test information between a POCT device and an information system. In February 2000, 49 healthcare institutions, POC diagnostic vendors, diagnostic test system vendors, and system integrators formed the Connectivity Industry Consortium (CIC) to address the POC integration problem. Since then, numerous technologies (e.g. Bluetooth and WiFi) have become available, which may facilitate improved connectivity in the hospital setting. In 2006, CLSI approved a new standard for connectivity (POCT02-A). This document provides the framework for engineers to design devices, workstations, and interfaces to allow multiple POC devices to communicate bidirectionally with access points, data managers, and LIS from a variety of venders. Table 12 lists several connectivity objectives promoted by the CLSI through the standardization process, which will help to optimize the postanalytical phases of POCT.

8 FUTURE TRENDS

8.1 New Practice Standard for Timeliness

Diagnostic efficiency increases as response time decreases and the cluster effectiveness of tests (or other diagnostic procedures) increases.[3,72] For a critical care profile, optimum response time is achieved when the combination of analysis time and transit time (a function of the distance of the measurement from the patient) is minimized. WBA fundamentally decreases response time by eliminating specimen centrifugation and other preanalytical steps. Process simplicity reduces errors. Current guidelines[1] recommend that rapid response testing should be available continuously during critical emergencies (such as cardiac arrest) and should achieve a turnaround time of 5 min or less from test ordering (actional, verbal, or written) to receipt of results by the clinical team. Immediacy of test results avoids empirical treatment, inefficient delays, and physiological obsolescence. Irrespective of where testing is performed, critical data must be both high quality and timely. POCT, that is, testing at or near the site of patient care, enables a new standard for rapid response diagnostic testing. This new standard is now accepted and expected in the practice of critical care medicine and in other fields of patient care.

Figure 13 Temporal optimization links rapid response and outcomes. The efficiencies inherent in either WBA or POCT can shorten not only the TTAT but also the interval between treatment and outcome, especially for critically ill patients.

8.2 Critical Speed, Test Clusters, and Medical Necessity

Rapid response shortens TTAT (Figure 13), the time from test ordering to treatment. Fast TTAT accelerates the speed of clinical decision making and diagnostic–therapeutic cycles. Where POCT is available, the recommended median response time for a critical care profile is 5 min.[1,95] In other situations deemed noncritical, it is efficient to fulfill negotiated response times specific to each clinical unit, care path, integrated protocol, or algorithm, with flexibility for individual physician and patient needs. Of course, results should be reported immediately. Technological advances, such as microfabrication, nanofabrication, and wireless technology will bring increasing numbers of networked quantitative tests, possibly as many as 50–100 on only one to three instrument platforms, to or near the bedside in the next 5–10 years, or sooner. These instruments can operate independent of a hospital environment (e.g. field conditions) or become networked into high bandwidth wireless connections compatible with telemedical systems.[94,96] The rapid development of whole-blood and biosensor-based instruments will make the use of conventional instrument platforms in critical care settings obsolete. Numerous qualitative test kits are currently available. POCT is becoming a ubiquitous aid to immediate diagnosis in the United States and abroad. However, POC test clusters must carefully target critical indications, based on medical necessity. The volume of testing should be reduced, while the relevancy should be increased. This impels the discovery of appropriate new diagnostic pivots (such as platelet function tests and multimarker indices), critical decision points, and integrated strategies, in order to avoid excessive costs.

8.3 Molecular Diagnostics

Molecular diagnostics can provide highly specific and sensitive methods for biomarkers and pathogens. As shown in the SeptiFast assay, molecular-based methods such as PCR can detect organisms where traditional methods failed. Future methods will utilize novel, thermal stable methods such as real-time, loop-mediated isothermal amplification (RT-LAMP) to detect nucleic acids without the need for thermocycling. RT-LAMP assays have been published for the detection of severe acute respiratory syndrome corona virus, West Nile virus, Newcastle disease virus, mumps virus, herpes simplex virus, *Porphyromonas gingivitis*, Rubella virus, and Epstein–Barr virus.[97–104] The isothermal nature of the RT-LAMP assay allows it to be used in the field and in disaster response.[105] Other developments may include quantitative nucleic acid testing (NAT). Quantitation will revolutionize infectious disease testing in critical care by allowing us to understand the pathophysiology of bacterial and fungal pathogen invasion and dissemination more clearly.[106] Pathogen kinetics may be revealed with quantitation and allow for monitoring of antimicrobial drug efficacy. Therefore, we may see future development in this area.

8.4 Recommendations for Point-of-care Glucose Testing

The increasing number of diabetics and the continued use of TGC in critically ill patients underscore the need for improved glucose monitoring technology. Performance standards for bedside glucose testing in hospital settings should adopt more strict and unbiased methods such as LS-MAD with a consensus error tolerance (Table 7). POCT teams should evaluate performance and cost effectiveness in the context of tight glucose control, therapeutic decisions, and outcomes in critical care. Future guidelines should include LS-MAD curve pattern recognition when assessing accuracy; LS-MAD theory can be applied to other POC tests, each with their own unique accuracy standard. LS-MAD curves are drawn on the unique human ability to recognize patterns quickly and discriminate performance visually. Both health care personnel (e.g. POC coordinators, critical care physicians, and nurses) and licensing agencies such as the FDA should require ISO 15197-integrated Bland–Altman and LS-MAD curve plots with highlighted discrepant values and erroneous results explained before validating POCT devices. Additionally, different brands of clinical laboratory analyzers and POC glucose devices intended for hospital use, specifically for acute care, should be standardized. These standards should be accuracy based rather than consensus based.

8.5 The National Institutes of Health Point of Care Research Network

In 2006, the National Institutes of Health (NIH), Institute of Biomedical Imaging and Bioengineering put forward a request for applications for the point-of-care technologies research network (POCTRN). The goal of the network is to build expertise in the development of integrated systems that address unmet clinical needs in POCT through the creation of multidisciplinary partnerships.[107] In 2007, four sites were selected including Johns Hopkins University, PATH, the University of Cincinnati, and the University of California Davis – Lawrence Livermore National Laboratory. Each site will have its own theme and is responsible for five cores: (i) development of prototype POC devices that match the center theme, (ii) identification of collaboratory exploratory projects, (iii) clinical needs assessment and dissemination, (iv) training, and (v) administration.[107] Center principal investigators, center websites, and the center-specific themes are shown in Table 11.

Core 1 provides research and development of new POC systems by the Center itself and facilitates clinical evaluation of novel POC designs that emerge from core 2 exploratory projects conducted external to the center. Core 2 will combine the resources of all four

Table 11 The NIBIB point-of-care technologies research network centers

Principal investigators	Center location	Theme
Fred Beyette www.ece.uc.edu/POC-CENT/	University of Cincinnati	Emerging neurotechnologies
Charlotte Gaydos www.hopkinsmedicine.org/medicine/std	Johns Hopkins University	Sexually transmitted diseases
Gerald Kost www.ucdmc.ucdavis.edu/pathology/poctcenter/	UC Davis – Lawrence Livermore National Laboratory (LLNL)	Rapid multipathogen detection for POCT and national disaster readiness
Bernard Weigl www.path.org/dxcenter/index.php	PATH, Seattle and the University of Washington	POC diagnostics for global health

NIBIB, National Institute of Biomedical Imaging and Bioengineering; NIH, National Institute of Health; POCTRN, Point-of-Care Technologies Research Network.

sites to solicit, select, and evaluate exploratory projects outside the POC Technologies Research Network. Core 3 assesses diagnostic testing needs to better understand POC technologies that Centers should produce. Results form the basis for soliciting exploratory projects and are disseminated broadly to technology developers and thought leaders. The purpose of core 4 is to train future scientists, engineers, and physicians to become experts in the practical use of POCT. Core 5 oversees the conduct of these four cores and integrates centers in the POCTRN.

8.6 Connectivity for Medical Response to Disasters

Telehealth embedded knowledge packets, in conjunction with POCT strategically placed in small-world networks for regional health care delivery, may provide multilingual education and intellectual connectivity at levels of sophistication appropriate for the practice of modern evidence-based medicine worldwide.[108] Appropriate telehealth integration with respect to demographics and topographies can provide efficient critical, emergency, and disaster care. For example, the NIH-funded wireless internet information system for medical response to disasters (WIISARD).[74] This program used sophisticated wireless technology to coordinate and enhance care of mass casualties in a terrorist attack or natural disaster and constructed a wireless first responder handheld device for rapid triage, patient assessment, and documentation during mass casualty incidents. Additionally, WIISARD integrated 802.11 wireless technologies for a blood pulse oximetry system, and developed an intelligent 802.11 triage tag for medical response to disasters. Ultimately, systems like WIISARD can link together responder wireless devices, patient wireless devices, medical visualization systems, disaster databases, and hospitals into one network. These systems should conform to unitary standards such as those proposed by CLSI (Table 12).[109]

8.7 Knowledge Optimization

Temporal optimization of diagnostic testing focuses on disease evolution and compresses its resolution. Temporal optimization is based on the fact that biochemical variables are coupled or linked, fundamentally, to pathophysiological changes at the cellular level and, ultimately, to patient outcomes. Outcomes integrate preceding effects (Figure 14). Therefore, integration is needed to improve outcomes. Evidence shows that POCT is medically efficacious when integrated within patient-focused protocols, care paths, and treatment algorithms. These approaches streamline essential information and are cost effective in critical care. Prevention of critical problems through early detection yields the greatest medical and economic awards, and is an important area for future development. By targeting surrogates of adverse outcomes, performance maps[70] increase the likelihood of early detection and prevention of sublethal and lethal events. Optimization synthesizes knowledge components. Therefore, you need to synthesize to enhance optimization. The synthesis of temporal optimization and optimization of diagnostic–therapeutic processes[70] produces knowledge accessibility, efficiency, and linkages that are vital to the diagnosis, management, and treatment of critically ill patients. The current shift to POCT points beyond simple efficiency to Knowledge Optimization® in the practice of critical care medicine.

8.8 Enhanced Performance Despite Economic Constraints

Medicine is facing increasingly tough competition in the marketplace. Fiscal constraints challenge our ability to provide the highest quality patient care. At the same time, the clinical team must conserve resources, do more with less, do it faster, and simultaneously improve outcomes. Shortened hospital stays, particularly critical care episodes, are essential. This urgency calls

Figure 14 POCT, sublethal/lethal surrogates, and integrated outcomes. The goal is to improve integrated medical and economic outcomes through decreased patient acuity, criticality, morbidity, and mortality. POCT is efficacious when sublethal and lethal surrogates are targeted for early detection and correction, which facilitate prevention and optimization before adverse events can feed forward to untoward outcomes.

Table 12 Connectivity objectives for POCT

Managers, operators, users, and patients

- Ease of use of devices, interfaces, and information (fully integrated with the LIS and HIS)
- Accelerated adoption of point-of-care technologies
- Interoperability with commercial and public domain software (cost savings)
- Facilitated performance enhancement, quality compliance, and training (QC/QA)

Interfaces and networks

- Standardized device docking platform and connections at the point of care (wireless best)
- Use of existing hospital network and computer infrastructures
- Improved regional communications (patient-focused care centers, urgent care, home, and others)

Informatics

- Effortless, fast, and seamless uploading and downloading (forced, if elected)
- Maximum information density and optimized data content (patients, test orders, results, and billing)
- User-configurable informatics use model

Communications

- Bidirectional transmission of instrument, quality, patient, and test result information
- Acceleration (not deceleration) of point-of-care processes (pre- and postanalytical phases)
- Security appropriate for devices, operators, patients, medical records, and legalities

Outcomes

- Faster TTAT and critical results notifications
- Faster, easier, and more complete data retrieving, mining, sharing, analyzing, trending, and managing
- Information consolidation and condensation for outcomes optimization

Source: First meeting of the CIC, Redwood City, CA, October 20, 1999. See www.poccic.org.

for progressive strategies that enhance both personal and team performance, such as using POCT to target surrogates of sublethal and lethal events, potentially reducing morbidity and mortality, and to conserve blood volume, thereby decreasing the need for transfusions, diminishing patient risks and eliminating ''downstream'' and ''hidden'' costs.

The prevention of adverse outcomes benefits the entire health system. Enhanced personal performance, however, depends on accelerated cognitive functions and decision making, and a reduction in the amount of poorly focused, unnecessary, or obsolete information. The new intensive care mosaic combines *in vitro*, *ex vivo*, and *in vivo* multimodal testing and monitoring. Continuous *ex vivo* and *in vivo* monitoring (with telemetry) can be expected to augment critical knowledge. Ultimately, judicious and cost-effective use of these three modalities will lead to continuous improvement in the quality of patient care, despite the financial constraints imposed by managed care and restructured health systems.

8.9 Outcomes Optimization and Future Challenges

Optimization of global POCT requires the development of quantitative technologies, new whole-blood standards, harmonization among standards, and improved quality control.[106,110] This optimization enhances critical knowledge of temporal trends (e.g. lactate), diagnostic–therapeutic patterns (e.g. Ca^{++}), unanticipated changes (e.g. Na^{+}), and organ injury (e.g. cardiac injury markers). Algorithms, performance maps, and new knowledge structures that facilitate synthesis need to be formalized for analytes, clinical problems, and critical care scenarios.[15,16] Formal optimization will be needed when treatment is automated using closed-loop feedback systems and *ex vivo* or *in vivo* patient monitoring. It will be necessary to assess efficacy and to determine, based on medical necessity, whether the changes in practice patterns are economically sound. However, published data indicate that POCT facilitates immediate evidence-based medical decisions and improves patient outcomes in the operating room, the intensive care unit, and other settings.

9 CONCLUSIONS

The hybrid laboratorian focuses on providing healthcare directly as a collaborative member of the clinical team. Therefore, outcome optimization forms a solid basis for setting priorities for the laboratory support of critical care. The new challenge of advancing technology and communication is how to use immediate diagnostic information to improve medical and economic efficiency (Table 13). The focus shifts to trends in information and patterns of change. The currency of the future will be organized knowledge. POCT is a knowledge technology. Networked POCT can organize data packets quickly to provide the right information to the right person

Table 13 Future directions for POCT

- Advancing technology and communication
  - New whole-blood assays, biosensors, and tests (e.g. organ injury markers)
  - Nanotechnology and modularity
  - Noninvasive and minimally invasive monitoring
  - Wireless bidirectional communication
  - Seamless informatics and tracking
  - Uniform regulations and connectivity standards
- Improving medical and economic efficiency
  - Flexible test menus, patient-focused test clusters, and increased pivotal test results
  - Clinical test ranges spanning critical limits (critical values, panic values)
  - Blood volume conservation and biohazard containment
  - Practice standards for fast TTAT (accreditation-required rapid response)
  - Cost effectiveness and peer comparisons (using local, regional, and national databases)
- Integrating knowledge and decisions (Knowledge Optimization®)
  - Diagnostics driven by POCT (increased useful tests, decreased useless tests)
  - Smarter *in vitro*, *ex vivo*, and *in vivo* systems guided by expert systems (artificial intelligence)
  - Simultaneous trending of biochemical and physiological variables
  - Total connectivity of devices, computerized systems, and information
  - Direct physician alerting and real-time decision making (reduced stat testing)
  - Clinical research, evidence-based care, and outcomes optimization
- Disaster preparedness
  - Prepare for regional disasters (e.g. ''newdemics'') by using POCT to facilitate the practice of on-site evidence-based medicine in small-world networks.
  - Develop POC technologies that withstand environmental extremes – high temperature, freezing, long-term humidity, dust exposure, mechanical shock, and different altitude
  - Establish field operating standards that manufacturers must meet to certify POC devices, monitors, and reagents for use in disasters
  - Equip US DMATs with POCT, train members in its use, and validate skills under simulated disaster conditions
  - Determine which tests DMATs need and which instruments they carry by matching treatment capabilities
  - Provide POCT on mobile units (land based, helicopters, and ships) to circumvent obstacles in different geographic and topographic settings

at the right time. Therefore, POCT can quickly create results that are medically valuable in critical care and other medical settings through integrating knowledge and evidence-based decision making.

ABBREVIATIONS AND ACRONYMS

ACT	Activated Clotting Time
ALP	Alkaline Phosphatase
ALT	Alanine Aminotransferase
ANOVA	Analysis of Variance
aPTT	Activated Partial Thromboplastin Time
ARDS	Adult Respiratory Distress Syndrome
ASOS	Analyte-specific Optical Sensor
AST	Aspartate Aminotransferase
ATI	Automated Testing Instrument
ATM	Automated Testing Machine
β-hCG	Beta-human Chorionic Gonadotropin
BNP	B-type Natriuretic Peptide
BUN	Blood Urea Nitrogen
CAP	College of American Pathologists
CBC	Complete Blood Count
CDR	Clinical Data Repository
CIC	Connectivity Industry Consortium
CK	Creatine Kinase
CK-MB	Creatine Kinase-MB isoenzyme
CLIA'88	Clinical Laboratory Improvement Amendments of 1988
CLSI	Clinical Laboratory Standards Institute
CPB	Cardiopulmonary Bypass Surgery
cTnI	Cardiac Troponin I
DMAT	Disaster Medical Assistance Team
DNA	Deoxyribonucleic Acid
E3G	Estrone-3-glucuronide

ECS	Electrical Conductance Sensor
FDA	Food and Drug Administration
FHHb	Fraction of Deoxyhemoglobin
FmetHb	Fraction of Met-hemoglobin
FRET	Fluorescent Resonance Energy Transfer
GD	Glucose Dehydrogenase
GGT	Gamma Glutamyl Transferase
GMS	Glucose Monitoring System
GO	Glucose Oxidase
GOT	Glutamic Oxaloacetic Transaminase
GPT	Glutamic Pyruvic Transaminase
HBV	Hepatitis B Virus
HCFA	Health Care Financing Administration
hCG	Human Chorionic Gonadotropin
Hct	Hematocrit
HCV	Hepatitis C Virus
HDL	High-density Lipoprotein
H-FABP	Human-type Fatty Acid–Binding Protein
HHb	Deoxyhemoglobin
HIS	Hospital Information System
HIV	Human Immunodeficiency Virus
HNTT	Heparin-neutralized Thrombin Time
HRP	Horseradish Peroxidase
INR	International Normalized Ratio
ISE	Ion-selective Electrode
ISO	International Organization of Standards
JCAHO	Joint Commission on Accreditation of Healthcare Organizations
Lac	Lactose
LAMP	Loop-mediated Isothermal Amplification
LD	Lactate Dehydrogenase
LDL	Low-density Lipoprotein
LED	Light-Emitting Diode
LIS	Laboratory Information System
LR-ACT	Low-range Activated Clotting Time
LS-MAD	Locally Smoothed Median Absolute Difference
MBTH	*meta*(3-Methyl 2-benzothiazolinone hydrazone)–*N*-sulfonyl benzenesulfonic acid
MetHb	Met-hemoglobin
MIP-3	Macrophage Inflammatory Protein-3
MRSA	Methicillin Resistant Staphylococcus Aureus
NDMS	National Disaster Medical System
NGAL	Neutrophil Gelatinase-associated Lipocalin
NIBIB	National Institute of Biomedical Imaging and Bioengineering
NIH	National Institute of Health
NT-proBNP	N-terminal pro-B-type Natriuretic Peptide
PBC	Protein Band Cassette
PBD	Protein Band Dipstick
PCA	Portable Clinical Analyzer
pCO_2	Partial Pressure of Carbon Dioxide
PCR	Polymerase Chain Reaction
PDAO	Protamine Dose Assay
pO_2	Partial Pressure of Oxygen
POC	Point-of-care
POCT	Point-of-care Testing
POCTRN	Point-of-Care Technologies Research Network (NIBIB, NIH)
PQQ	Pyrroloquinoline Quinone
PSA	Prostate Specific Antigen
PT	Prothrombin Time
PTCA	Percutaneous Transluminal Coronary Angioplasty
PTD	Personal Testing Device
RACT	Recalcified Activated Clotting Time
RT-LAMP	Real-time, Loop-mediated Isothermal Amplification
SARS	Severe Acute Respiratory Syndrome
SERS	Surface-enhanced Raman Spectroscopy
sO_2	Oxygen Saturation
SO_2%	Percent Oxygen Saturation
SSE	Substrate-specific Electrode
tBil	Total Bilirubin
TC	Transcutaneous
TCM	Transcutaneous Monitoring
TCO_2	Total Carbon Dioxide
TEG	Thromboelastography
TGC	Tight Glycemic Control
tHb	Total Hemoglobin
TnI	Troponin I
TPA	Tissue Plasminogen Activator
TpP	Thrombosis Precursor Protein
TSH	Thyroid Stimulating Hormone
TT	Thrombin Time
TTAT	Therapeutic Turnaround Time
USOSHA	United States Occupational Safety and Health Administration
WBA	Whole-blood Analysis
WBC	White Blood Cell Count
WIISARD	Wireless Internet Information System for Medical Response to Disasters

APPENDIX

Table A CLIA-Waived Tests (109 Total Tests)

Analyte Name
Adenovirus
Aerobic/anaerobic organisms – vaginal
Alanine aminotransferase (ALT) (SGPT)
Albumin
Albumin, urinary
Alcohol, saliva
Alkaline phosphatase (ALP)
Amines
Amphetamines
Amylase
Aspartate aminotransferase (AST) (SGOT)
B-type natriuretic peptide (BNP)
Barbiturates
Benzodiazepines
Bilirubin, total
Bladder tumor associated antigen
Blood lead
Calcium, ionized
Calcium, total
Cannabinoids (THC)
Carbon dioxide, total (CO_2)
Catalase, urine
Chloride
Cholesterol
Cocaine metabolites
Collagen type i crosslink, *n*-telopeptides (NTX)
Creatinine
Erythrocyte sedimentation rate, nonautomated waived
Estrone-3 glucuronide
Ethanol (alcohol)
Fecal occult blood
Fern test, saliva
Follicle stimulating hormone (FSH)
Fructosamine
Gamma glutamyl transferase (GGT)
Gastric occult blood
Gastric PH
Glucose

Table A *(continued)*

Analyte Name
Glucose monitoring devices (FDA cleared/home use)
Glucose monitoring devices (prescription use only)
Glucose, fluid (approved by FDA for prescription home use)
Glycated hemoglobin, total
Glycosylated hemoglobin (HGB A1C)
HCG, urine
HDL cholesterol
Helicobacter pylori
Helicobacter pylori antibodies
Hematocrit
Hemoglobin
HGB, single analyte inst. W/self-cont. . .
HIV antibodies
HIV-1 and HIV-2 antibodies
HIV-1 antibody
Infectious mononucleosis antibodies (mono)
Influenza A
Influenza A/B
Influenza B
Ketone, blood
Ketone, urine
Lactic acid (lactate)
LDL cholesterol
Leukocyte esterase, urinary
Lithium
Luteinizing hormone (LH)
Lyme disease antibodies (*Borrelia burgdorferi* ABS)
Methadone
Methamphetamine/amphetamine
Methamphetamines
Methylenedioxymethamphetamine (MDMA)
Microalbumin
Morphine
Nicotine and/or metabolites
Nitrite, urine
Opiates
Ovulation test (LH) by visual color comparison
Oxycodone
Phencyclidine (PCP)
Platelet aggregation

Table A (*continued*)

Analyte Name
Potassium
Propoxyphene
Protein, total
Prothrombin time (PT)
Respiratory syncytial virus
Semen
Sodium
Spun microhematocrit
Streptococcus, group A
Thyroid stimulating hormone (TSH)
Trichomonas
Tricyclic antidepressants
Triglyceride
Urea (BUN)
Uric acid
Urine dipstick or tablet analytes, nonautomated
Urine HCG by visual color comparison tests
Urine qualitative dipstick ascorbic acid
Urine qualitative dipstick bilirubin
Urine qualitative dipstick blood
Urine qualitative dipstick chemistries
Urine qualitative dipstick creatinine
Urine qualitative dipstick glucose
Urine qualitative dipstick ketone
Urine qualitative dipstick leukocytes
Urine qualitative dipstick nitrite
Urine qualitative dipstick PH
Urine qualitative dipstick protein
Urine qualitative dipstick specific gravity
Urine qualitative dipstick urobilinogen
Vaginal PH

Clinical assays have an important role in medical decision making. Test results help a clinician answer a fundamental question, ''how should I treat the patient?'' Whereas these assays used to be developed in hospital laboratories and were performed by skilled technicians, the availability of automated instruments has created an industry which now provides most of the assays. The industry is highly competitive – development of assay systems requires a product development process that is efficient. Most companies use a development process that breaks product development into stages: (1) researching new opportunities, (2) proving feasibility, (3) scheduled development, (4) validation, and (5) product launch. Each stage has methods and tools that help attain the commercial goal.

1 INTRODUCTION

1.1 Brief History of Clinical Assays

Although clinical assays of some form or another can be traced back to antiquity, it was not until the mid-1800s, as the knowledge of chemistry improved, that urine chemistry tests were developed for glucose and urea.[1] Tests for blood samples were enabled by the invention of the hypodermic syringe in 1845. Assays for glucose in blood were aided by the development of the colorimeter. Jaffe's picric acid reagent for creatinine was published in 1886. In the 1920s and 1930s a spectrophotometric assay of nicotinamide adenine dinucleotide (reduced form) (NADH) was used to determine LDH (lactate dehydrogenase). During the 1950s, a variety of different

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

technologies were invented or perfected, including blood-gas analysis, flame photometry, and electrophoresis of proteins. Immunoassays became possible owing to the invention of radioimmunoassay by Berson and Yallow.

A salient feature of virtually all assays performed during the 1950s was the labor-intensive and technique-sensitive properties of the assays. This restricted the number of assays that could be reasonably performed and also caused quality problems.

1.2 How the AutoAnalyzer Changed the Landscape

In 1957, Skeggs provided the basis for a new industry with the invention of the AutoAnalyzer.[2] The concept was commercialized by Technicon Instruments.

Early automated analyzers were continuous-flow devices. Samples were aspirated through tubing connected to a pumped stream of reagents. The tubing was coiled to allow time for the reagents to react, after which the solution passed through a flow cell which was part of a colorimeter.

The value of the AutoAnalyzer and the instruments that followed, including those used today, is the automation of difficult, labor-intensive steps. This has made laboratory assays cheaper to perform and improved their quality. A typical clinical chemistry device can be considered a robot (or series of robotic devices) controlled by a computer that delivers and moves precise amounts of fluid. With automation, the volume of tests skyrocketed and the founder of the company best known for the initial automation – Technicon – became one of the wealthiest men in the world.

In those days, product development was much simpler than today. Assays could be designed by a single person (the pieces of an AutoAnalyzer cartridge could be assembled like Lego blocks and, although somewhat of an exaggeration, it was boasted that an assay could be developed in the morning, tested in the afternoon, and introduced into the customer training laboratory that evening). Since these early days, the science has advanced, products are more complex, and competition and regulation are part of the landscape. Technicon lost its leadership in the diagnostics field and was sold several times. The purpose of this article is to describe how product development for clinical assays is carried out in this new environment.

1.3 The Current Technical, Commercial, Medical, and Regulatory Dimensions of the Product Development Environment

1.3.1 The Technical Environment

The medical device industry's biggest technical challenge is not mastery of any single technology but rather the *integration* of many complex and diverse technologies such as:

- software including real-time systems, user interfaces, complex algorithms that convert raw signals to concentrations, databases, and communication software;
- hardware including electromechanical, optical, and fluidic systems;
- biochemical reagents, many of which are unstable to heat or light.

Competitive pressures require companies continually to launch new products to remain successful. Technical management is challenged with reducing the length of the product development cycle while meeting product and quality specifications.

1.3.2 The Competitive Environment

The medical device industry was a $20.5 billion industry in 1997 and is expected to grow to $27.5 billion in 2002. As with many competitive environments, successful companies need to anticipate technical trends or technical upsets, and also changing customer demands. Products need to have short development cycles. Since many governments are trying to lower healthcare costs, medical device systems have to be productive. The industry has favored consolidation, so competitors often can leverage expertise in several technical domains and have international sales organizations with efficient distribution channels.

There is a range of product opportunities from commodity types such as routine clinical chemistry analyzers that assay for substances such as cholesterol and glucose to new markers derived from genomics research. Marker concentrations range from millimolar to the ultimate goal of single-molecule detection.

Although there are many patents in the field, few confer a long-term competitive advantage [hepatitis C virus (HCV) is an exception]. Most new products are replicated in some fashion by competitors, hence there is a narrow window of higher profits followed by a return to a near commodity market.

There is a range of ease of sample preparation with the most complex being serum and plasma, followed by whole blood (centrifugation of the sample not needed), then urine, whole blood and urine home use, and finally non-invasive testing.

Market segments include large, national reference laboratories, hospital laboratories, hospital satellite laboratories (''point of care testing'' within the hospital), doctors' offices, and home testing. Each market segment has different primary and secondary customers to be satisfied, which include:

- end users, i.e. the people who conduct tests in hospital laboratories, reference laboratories, doctors' offices, and the home;
- all people involved in the buying decision, ranging from group purchasing agents to home users;
- clinicians and patients;
- regulatory agencies.

2 PRODUCT DEVELOPMENT AS PART OF THE COMMERCIAL HIERARCHY

2.1 Company Vision, Mission, and Business Strategy

Most companies have a hierarchical method of running their business; they include a vision and mission statement, a business strategy, a technology strategy, and a product development process (see Figure 1). The position of the hierarchy depicted in Figure 1 is proportional to the amount of effort required to create each item. Thus vision statements are easy to create, mission statements more difficult, and strategies even more difficult. It has been said that a vision without a strategy is simply a dream.

2.2 Technology Strategy

There is often no clear demarcation between a business and a technical strategy. In some companies a business strategy contains the technology strategy. Either a business or a technology strategy can provide a leadership role. For example, if a business strategy specifies being an efficient "follower", then efficiencies will be valued not innovative technologies. Yet, if there are technical strengths in the organization, a business strategy may revolve around technology. In either case, valuing individual opportunities and the entire portfolio of opportunities *selected* is a key task of a technology strategy.

Figure 1 Hierarchical nature of business processes.

2.3 Use of Portfolio Analysis to Select Research and Development Products to Fund

Since virtually all companies have limited funds, there has to be a way to select which projects to fund. Decision analysis is a fundamental building block for this task. This method will be discussed in section 4.3.

3 THE FIVE STAGES OF PRODUCT DEVELOPMENT

3.1 Overview of Each Stage

Many companies use a stage gate system where product development is divided into several stages.[3] At the end of each stage, a decision is made based on the results, whether or not to fund the next stage. (Often in practice, these funding decisions are not associated with the stage gate system.) This system is popular, even if it is partially implemented, because it serves as a useful communication vehicle. As consolidation of the industry continues and projects become larger and more complex, this communication aspect is important. Although the names and numbers of stages may differ in different companies, the distinct stages to this process are briefly defined below.

3.1.1 Stage I: Preliminary Assessment: Researching New Opportunities

In this stage, companies decide which projects to commercialize. Generally, this stage does not include basic research, which is usually decoupled from a product development process. On the other hand, applied research is part of the stage. It may consist of evaluating opportunities from within the basic research division of the same company or from other companies or universities. Many products that are commercialized are licensed from external sources, so that often initial studies are directed to understanding the value of these technologies or assessing the likelihood of technical success.

Studies at this stage are often carried out by modeling. Concomitant with these activities is the use of decision analysis to value individual product opportunities and portfolio analysis to select a set of projects to fund.

3.1.2 Stage II: Detailed Assessment: Proving Feasibility

The decision has been made to commercialize the product. The first step, which is often started and in

some cases completed in Stage I, is to specify the product. There is usually a hierarchy of specifications which flow down from concept to user to technical specifications. The basic task is simple: find out what the customer wants. Techniques used include surveys, focus groups, and conjoint analysis. Quality function deployment (QFD) is a method that translates customer requirements throughout the product development process. At the end of Stage II, studies are conducted to ''prove feasibility''. Companies struggle with defining feasibility, since at this stage release requirements are often not met.

3.1.3 Stage III: Scheduled Development

In Stage III, the lion's share of product development takes place. For diagnostic companies, there are basically two major development paths, assays and instruments. Within assay development, designed experiments often yield robust products faster. For instruments, reliability growth management has proven to lead to faster attainment of reliability goals. Software, while part of the instrument development, is an ever-increasing task. System integration, making the reagent–instrument system work, takes place – whether reagents or instrument work independently is of limited value. In manufacturing, design for assembly (DFA) tools are used. Initial customer trials are performed.

3.1.4 Stage IV: Validation

Customer trials continue and become more formal. Concomitantly, extensive internal studies are carried out to validate assay performance, instrument reliability, and ease of use. Software is formally validated. During this stage, there is often intense pressure to launch the product, hence tradeoffs are made between features (including meeting original specifications) and the product launch date.

3.1.5 Stage V: Commercialization: Product Launch

As the product is launched, marketing campaigns position the product, customer training is carried out and product claims are issued which form the basis of warranty policies. Product-support strategies are deployed to deal with customer issues. Since some product features have been deferred to meet a launch date, they are now developed as are cost-reduction programs.

3.2 How Companies Manage the Process

Many companies use the stage gate system described in section 3.1. Organizationally, companies are set-up from centralized research and development (R&D) to decentralized business units, each containing R&D to in-between organizations. Companies need both good processes and good people. Whereas highly skilled managers previously could overcome poor processes, this is becoming more difficult owing to the complexity and larger scope of projects.

Leadership skills require domain knowledge. One does not have to be a domain expert but should have sufficient knowledge of major techniques and strategies (e.g. more than knowing the buzzwords) to be able to define or review technical strategies not only at a company wide level but also at the project level. Relentless and effective questions – using the scientific method – demanding data rather than relying on anecdotal evidence are often features of successful leaders.

Successful companies often have a process which enables good decisions to be made based in part on quantitative analyses and on a review system that provides checks and balances. The use of quantitative analyses to improve decision making does not replace the judgment and intuition needed. Yet, there can be a danger of foregoing the use of quantitative analyses. A manager who asks, ''what does your gut tell you?'', as his or her primary decision tool is often ignoring valuable information that cannot be gained from intuition or judgment alone. On the other hand, it is also unwise to rely solely on quantitative methods. There is an old adage, ''beware of the phenomenon statistics on, brain off''. Hence, judgement is always used and aided with quantitative analyses.

3.3 Key Metrics to Monitor Progress

Whereas scores of metrics are used by program managers to track project progress, there are only a few key metrics that are needed. Ideally, each of these will have some predictive ability. The goal of the metrics is to alert management of problems (schedule, budget) long before they happen so that contingency plans can be deployed. Management's nightmare is to be told of problems the night before a milestone completion date. Examples of key metrics that should be available for review during the entire project (and updated at appropriate intervals) are:

- a net present value (NPV) analysis of the project's product (note that a well-constructed NPV analysis will include all of the bulleted items below);
- the predicted launch date;
- the total development cost and standard cost;
- the predicted service-call rate or other quality measures such as the predicted complaint rate;
- any other key project specific metrics unique to the product, but limited in number.

One metric that should be avoided is ''percent completed'', because it is misleading. If task completion times were uniformly distributed, then percent completion would be meaningful because a project that was 50% complete would require twice as much time to be 100% complete. For technology projects, there are always unanticipated problems which cause task completion times to have a skewed distribution.[4]

Of course, not every important product feature can be quantified. These should not be ignored but their subjective nature should be realized.

4 STAGE I: PRELIMINARY ASSESSMENT: RESEARCHING NEW OPPORTUNITIES

4.1 The Spectrum of Basic Research to Product Licensing

Companies can be innovative in various ways. It makes little difference if a successful product were developed totally internally or licensed as a (virtually) final product.

Basic research attempts to understand phenomena within an area, without specific product goals. Basic research questions can be more narrowly focused to become applied research. With the appropriate staff, organizations can monitor basic or applied research conducted in other companies or in universities, with the idea of licensing. Licensing can include licensing a basic concept which needs significant applied research for commercialization. Alternatively, a licensed technology may not require any significant development.

4.2 The Use of Modeling and Empirical Experimentation

There is a desirable hierarchy to follow for efficient product development. For example, in the technology evaluation phase, if one has sufficient knowledge, physical modeling can be applied to determine whether a new technology will work. Modeling is attractive because it can give answers relatively quickly and inexpensively. For example, if one has dose-precision goals for an immunoassay and a dose–response curve, one can model, using propagation of errors, whether the dose–response curve is adequate to fulfill the precision goals. If there is insufficient knowledge to permit modeling, designed experiments are an efficient way to assess technology. One-at-a-time experiments are also useful when used to build knowledge.

4.3 Use of Decision Analysis to Value Individual Product Opportunities

The goal of companies is to be profitable. The goal of profitable companies is to be more profitable. In high-tech companies, such as those in medical diagnostics, profit is fueled by new products. Yet all new products are not profitable enough, nor can companies afford to develop all conceivable projects.

Decision analysis is a method to provide decision makers with information to help inform the decision on whether to fund a project.[5] It can be broken down into two phases, an initial set-up phase and an ongoing phase used for each subsequent valuation. The initial phase starts with determination of the frame or the boundaries of the opportunity, followed by an influence diagram, which represents a high-level abstraction of the drivers that contribute to the desired output measure: NPV of cash flows. Cash flow is more important than profit because companies can be profitable with negative cash flow and still go out of business. Influence diagrams set the granularity for the data collection needed for the financial model. The influence diagram is converted into a decision tree, which is then converted into a financial model, often in a spreadsheet form. Key to the decision tree is the use of probabilities to deal with uncertainty. Often a 10–50–90 approach is used, where 10 represents a 1 in 10 chance that the value could be as low as some value, and likewise 90 represents a 1 in 10 chance that the value could be as high as some value. The fundamental exercise in decision analysis, which is conducted in the ongoing phase, is to solicit valid data for all of the inputs. This enables a ''base case'' NPV to be calculated.

Sensitivity analysis is a technique to determine which input variables have the most risk towards NPV. For example, if a product were launched early, its NPV might be $100 million and if launched late, its NPV might be $5 million. In this example, time to market is a risk factor for this program. The results of a sensitivity analysis are often graphed in a bar chart known as a Tornado diagram (see Figure 2).

Scenario analysis takes the top risk factors found from a sensitivity analysis and calculates the NPV for all combinations. Thus, if there were four input factors, each with three levels, there would be 81 calculated NPVs. The probability weighted average of NPVs is known as the expected NPV. One can also evaluate the range of NPVs as a measure of risk.

If one has conducted NPV analysis for each opportunity, one can conduct portfolio analysis to select which projects to fund. This is usually done with linear programming algorithms since there will be several constraints to the problem, such as specifying for each year the minimum cash flows and maximum costs. There may be additional constraints related to strategy or discrete jumps in project funding. Graphs to support these analyses include a graph of technical risk vs commercial return, and a graph of cumulative development cost vs cumulative commercial return (productivity curve – see Figure 3).

Figure 2 Tornado chart example. IVD, in-vitro diagnostic.

5 STAGE II: DETAILED ASSESSMENT: PROVING FEASIBILITY

5.1 Specifying the Product with Focus Groups and Conjoint Analysis

Engineers and scientists develop a product to meet requirements. These requirements, also called specifications or goals, are important since if they are incorrect the product may fail because it is not what the customer wants. If the specifications are too stringent, product release may be delayed, making the project less profitable.

Whereas it is enticingly simple in concept to find out what customers want, it is surprising difficult in practice. There can be internal barriers to getting this knowledge. For example, if a designer is set on creating a complex design, he or she may be oblivious to finding out if customers value design as an important product attribute. Other organizational issues abound that challenge the

Figure 3 Productivity curve for R&D projects.

process of getting the right requirements. Even when these issues are absent, it is hard for manufacturers to get targets for goals because:

- manufacturers do not know how to ask for customer needs;
- users do not know how to talk about their needs.

Product attributes tend to fall into three categories as shown in Figure 4, often called a Kano diagram.[6] For some attributes, there is a proportional relationship between the quantity of the attribute satisfied and customer satisfaction. As an example, the more menu items are offered for an analyzer, the higher is the degree of customer satisfaction. A second category of attributes is not requested by customers, but when it appears, they are delighted. An example in this category would be the first time remote units were offered with televisions. In the last category, customers expect the attribute to be at a certain level – if it is higher they are not more satisfied but if it is too low, they are very dissatisfied. Product quality often falls into this category.

Figure 4 Kano diagram of different types of customer attributes.

5.1.1 Surveys and Focus Groups

Surveys would seem to be an easy way to elicit needs and to set targets. One simply asks customers. However, there are pitfalls. If one asks open-ended questions, such as, ''what are the clinically acceptable limits for a cholesterol assay?'', one could get vague responses such as ''no error'' or ''an error that does not cause diagnostic problems''. One remedy to this is to offer

multiple-choice questions. However, this is not foolproof either. Responses can be checked off without a guarantee that the question was correctly understood by the respondent. Moreover, respondents tend to want ''the best''. Thus, given a choice for the total error for cholesterol to be 1, 3, or 5%, many respondents will simply check off 1%. Skendzel et al. overcame many of these difficulties in a cleverly constructed survey.[7] Focus groups often consist of prototype products shown to customers with a description of features explained. There is then a discussion of the product led by a facilitator who ensures that questions get answered, there is no bias, and there is proper balance among the respondents.

5.1.2 Conjoint Analysis

In real life, one must make tradeoffs. One wants a car that is both luxurious and low priced. For laboratory assays, one wants low total error, low cost, high ease of use, high reliability, etc. For any of these situations, there will be acceptable compromises among the desired values of the goals. Conjoint analysis (also called multiattribute utility analysis) is a form of marketing research that provides a protocol and analysis method for estimating these tradeoffs.[8] Its idea is to present a customer with a series of assays, each with different values for various attributes. The customer ranks his preference for each of the assays. With several customers performing this ranking, the value of each attribute can be found by statistical analysis.

5.1.3 Use of Current Data

Given an assay that is in service, one can ask whether the complaint rate is low enough. A ''yes'' answer may signify that the assay's performance and reliability are adequate. One can then use this performance as a goal for a new version of the same or a similar assay. Of course, this method will not work for new analytes, for which there are no data. Moreover, the problem has not really been solved, it has been transferred. One must now decide what is a low-enough complaint rate.

5.1.4 Aids to Improve Goal Setting

Cause and effect diagrams (also called fishbone or Ishakawa diagrams) help to highlight potential problems and to focus goal setting for quality. The universe of potential quality goals must be narrowed down to those that have a reasonable likelihood of causing problems. Otherwise, the list of goals to be tested could be endless. Reviewing target settings is also important. For example, the goal of zero software bugs is inappropriate. Realistically, there will always be a measurable frequency of software bugs, even for the best systems. A goal of zero is unrealistic and not useful. A nonexistent goal, while a rather obvious category, crops up occasionally. An example is the lack of an outlier goal. Outliers are values that are so far away from the true values that they almost always cause problems. Yet, there is seldom a goal describing how far off a value must be to be called an outlier and how many outliers are acceptable. A goal requires a clear pass–fail criterion. This implies that a metric is in place which will be used to base the decision. Deciding on a metric is a step in agreeing on goals. A metric should be objective, easy to understand, and relevant to the goal.

5.2 Quality Function Deployment

One of the challenges in product development organizations is the variety of teams and personalities involved. There are people who are creative, those who are powerful and persuasive, and so on. To design and build a product that truly satisfies customer needs requires that the customer needs are always the most important priority in design decisions. But consider a powerful functional group (industrial design, for example). If the physical shape of a product is not ranked as important to customers, the powerful design group may nevertheless spend a great deal of time to design the perfect physical shape. This could constrain more important activities by draining scarce resources. QFD attempts to solve this problem by using tools to ensure that what is always heard is ''the voice of the customer'', not the voice of the manager.[9,10]

5.3 Prototyping Techniques for Instruments, Software, and Reagents

Prototypes are used in many of the product development domains. Prototypes are used to communicate ideas to management and potential customers and as a means of learning. Whereas modeling is a form of prototyping, physical prototypes represent an opportunity to expose problems that might be difficult to model.[11]

For hardware, prototypes are built with various levels of functionality focus on elements that require more information. For example, in blood-gas instruments, a new sample-entry method was tested as a prototype because its interaction with the user was different from previous models. In software, user interfaces are prototyped, often with languages such as Visual Basic that can be used by nonprogrammers.

Assays are also prototyped by developing ''laboratory'' lots of reagents on a breadboard or systems designed to model the intended platform.

5.4 What is Feasibility and Experimental Plans to Prove Feasibility

On an abstract level, feasibility is proving that something is technically possible, or conversely, proving that something is *not* technically possible. In these cases modeling based on physical laws will help.

On a more practical level, companies often struggle with the definition and measurement of feasibility. For example, if a product has been shown to meet all of its performance requirements, it is certainly ''feasible'', but if so why would it not at the same time be released for sale. Sometimes feasibility is defined so that a product must meet most of its specifications and be close to meeting the others. Yet, can we be sure that it will ever meet the other specifications? Another variation is to define feasibility as being able to do it once (e.g. with hand-machined parts or hand-formulated reagents). Again, this may not mean much if manufacturing can never make the product.

The bottom line is that each organization must use judgment to measure feasibility whatever definition is employed. For example, if some specifications are allowed to be missed, there must be a believable pathway to meet these specifications. This requires management to have sufficient domain knowledge.

What is still at risk after feasibility is not whether the product can be made but rather when it will be released. Thus, the risk has shifted from no product at all to one that is too late.

6 STAGE III: SCHEDULED DEVELOPMENT

6.1 Introduction

Whereas it would seem simple to turn loose a bunch a scientists and engineers to build products – that is what they are trained to do – there are usually management and other challenges which make this process more complicated. As mentioned, there are huge pressures to reduce the product development cycle time. Often ''quick'' experiments are favored over longer ones, even if the longer one ultimately lead to a shorter cycle time.

6.2 The Use of Experimental Design to Build Robust Assays Faster

Robust products are those that not only meet specifications but do so with each lot of raw materials and process variation.

Most scientists are not trained in the use of experimental design. They often work alone on problems, using creative thinking and hard work. Experiments are their best idea of a solution – this can and often does go on for long periods of time.

This type of experimentation does have a role in industry – sometimes simply trying one's best idea or using intuition will result in the fastest solution. This is particularly true when the state of knowledge is low. If, however, the state of knowledge is higher – but not high enough so that computer models can be built from physical laws – then empirical experimentation can be the fastest way to build robust products. Building robust products through empirical experimentation involves:

- *Flow charting* – A diagram of the process is constructed, where each step is identified. This works for manufacturing processes such as reagent formulation and also for the conceptual process of a sample moving through an instrument system.
- *Cause and effect diagrams* – Often facilitated through brainstorming sessions, cause and effect diagrams are similar to fault trees in reliability. They attempt to enumerate in a diagram all possible failure modes for each identified subsystem.
- *Screening experiments* – Given a large (8–20) possible number of variables that could affect a response, screening experiments are an efficient way to determine which of the factors have no effect and which have the most influence.
- *Factorial experiments* – Traditional experiments, also called one-at-a-time experiments, involve holding all factors constant except the one under study. This is repeated with all other factors. The end result is an ''optimized'' system. However, it has been shown that a more efficient experiment plan is to perform factorial and fractional factorial experiments. One-at-a-time experiments result in $(k+1)/2$ as many runs as factorial designs, where k is the number of variables. Moreover, there are cases where an optimum is much more likely to be reached with factorial experiments.[12]
- *Response surface experiments* – Response surface experiments allow more accurate models to be constructed by modeling second-order effects. This allows empirical equations to be developed which can serve as accurate response predictors within the response surface modeled.
- *Taguchi-type experiments* – These experiments are in fact factorial experiments, but have been developed to ensure that variation is modeled as a response in addition to location. The principle is that with natural manufacturing and raw material variations, the product should behave consistently. Formulation settings can be developed based on these experiments to provide product performance consistency.

6.3 Reliability Methods for Instrumentation

If our state of knowledge of medical diagnostic instrumentation were higher, we could design reliable systems on a computer. When actual systems were built, little testing would be required – in fact, the only test would be a demonstration test that essentially verified the computer model. Whereas this practice has been used in other industries such as for designing and building commercial airplanes, it is not appropriate for medical diagnostic systems because our state of knowledge is not high enough and the product design cycle is too short.

With these constraints, what has proven successful is use of the reliability growth management (MIL-HDBK 781a).[13] This process uses the test, analyze and fix (TAAF) process in which systems are tested in order to expose problems. A corrective action process is established to fix the problems. The process continues until the reliability goal has been met.

Other key elements are:

- *A reliability model* – The reliability metric that is measured after product release must be modeled so that it can be measured in-house. For example, unscheduled service calls may be the reliability metric that the business uses. It would be tempting to model this internally by simply counting how many times a gross failure occurs (e.g. power supply burn out). Yet if some less severe error occurs, from which a customer could recover, and this error occurs too frequently, this problem will also result in a service call and its behavior must be modeled.
- *Failure review analysis and corrective action system (FRACAS)* – This process, often supported by software, reviews the failures that have occurred. Failures are categorized and assigned to appropriate engineers to be fixed. A key element of this step is to prepare Pareto charts of failure modes so that problems to be tackled are selected which will have the biggest impact on improving reliability. When the corrective action is implemented, its effectiveness is monitored.
- *Idealized growth curve* – Given certain assumptions about the problem obtained from initial or historic data, a curve is constructed projecting reliability improvement with instrument cycles (e.g. cycles can be translated to calendar time).
- *Tracking curve* – Actual progress is tracked against the idealized growth curve using Duane or Army Material Systems Analysis Activity (AMSAA) models.

6.4 Design for Assembly

A system that is difficult to assemble will take longer to assemble and be more likely to be incorrectly assembled, both of which lead to higher manufacturing costs. DFA is a process that is used in design to reduce the number of parts and simplify the assembly process.

7 STAGE IV: VALIDATION

7.1 Internal Validation

Internal validations, often conducted by an internal, independent assessment group, are conducted to determine whether the product has met its specifications. There is still tremendous pressure to launch the product, so an efficient set of experiments is required. While specification assessment is the goal, ideally the evaluation will also find out any other problems that might occur with the product (which may not be contained in the set of specifications).

The design of the evaluation protocols has been an area of statistical development[14,15] and standard committees, e.g. National Committee for Clinical Laboratory Standards (NCCLS). As an example of an efficient protocol, the NCCLS protocol EP10A assesses five performance parameters, during each ten-sample run (three replicates of three concentration levels with a primer).[16] The parameters assessed include precision, bias, sample-to-sample carryover, linear drift, and nonlinearity. The key to this protocol is the sample order, which confers a near orthogonal relationship among the variables. Orthogonality is a desirable feature because it allows for ease of interpretation of results.

The set of protocols that are routinely performed to validate a system include:

- *Diagnostic efficacy* – Needed only for new markers, this expensive study establishes the proportion of test answers that correspond to the medical diagnosis (and the proportion of wrong answers, i.e. false positives and false negatives).
- *Method comparison* – Consists of running real or simulated patient samples across the range of the assay over a number of days. The comparison method can be a reference method or popular commercial method. The slope (proportional bias), intercept (constant bias), and scatter about the regression line are estimated.
- *Precision studies* – These are part of the method comparison but also run separately with controls to assess within-run and total precision. Total precision is the precision expected in ''long-term'' use. It ideally would include all possible sources of variation (hence the word ''total''). In reality, sources of variation such as different reagent and calibrator lots are often not included in this estimate.

- *Interference studies* – Whereas we would like to believe that assays are totally specific, virtually all assays suffer from interferences. Protocols to test for interferences usually involve running replicates of a sample spiked with the desired level of interference, compared with the sample spiked with diluent (the control). Establishing the candidate list of interferences requires knowledge of the assay weaknesses in addition to a current list of endogenous and exogenous substances in blood and their concentrations.
- *Sensitivity determination* – Some assays require an extremely low detection limit (for example, in infectious disease assays a single viral particle is sufficient to indicate disease). Sensitivity can be viewed as a precision assessment at zero concentration – the protocol involves running a set of zero concentration samples and or a dilution experiment starting at a low concentration.
- *Dilution* – Some substances have an observed range that spans several orders of magnitude. Human chorionic gonadotropin (hCG) is an example with an expected value of zero, a decision limit of 10 and an abnormal value of 10 000 or more. Often systems cannot directly assay samples spanning this range because the assay response curve does not cover this range. At some level of concentration, the dose–response curve is so flat that precise quantification is impossible. The system has to be able to measure samples after they have been diluted with various ratios of sample to diluent. It is expected that linearity is preserved as a function of dilution.
- *Other special studies* – Random access.

7.2 Customer Trials

Whereas customer trials are conducted throughout the product development cycle, there are issues which make their value somewhat limited. For products that have not been released, customers in the USA cannot report patient results. Thus, the answers provided by the assay cannot be used to help with medical decisions. Moreover, the customer has not purchased the system and it is not under warranty. Therefore, although the product is ''in the hands of the customer'' it is often paradoxically not used by the customer as it would be if the customer had actually purchased the system. Often the data collected at these trials are analyzed solely by the manufacturers, with the customer having a limited role in running samples. Note that a released product that is not approved by the Food and Drug Administration (FDA) may nevertheless be used to report patient results under an ''investigational use'' exemption.

These studies are nevertheless conducted and at times uncover issues that have been missed. The failures to detect these problems in-house may at times be due to unrepresentative sampling, or by using the system differently than a customer. For example, internally based technicians have learned how to work with new systems that have problems. These ''work-arounds'' are often complex and, when the system is field tested, the customer performs the work-arounds incorrectly, causing a system failure. Other issues could be uncovered by assaying samples that are not tested in-house. Testing samples in-house requires different processing to samples tested in a hospital, since shipment and storage are required for in-house samples.

7.3 Tradeoffs Between Product Launch Date and Features

Time-to-market pressure and technical problems force tradeoffs between launching the product ''as is'' or delaying launch to put in more features. The tradeoffs can be modeled with decision analysis tools.

8 STAGE V: COMMERCIALIZATION: PRODUCT LAUNCH

8.1 The Difference Between Product Claims and (Internal) Specifications

During product development, there is a set of product specifications that are used internally. When the product is released, the internal goals are transformed by the manufacturer into customer claims, which may or may not be the same as the internal goals. The claims represent a data source for customers, who can compare different manufacturers' claims. Of course, as most consumers are aware, not all claims are always met! There is an additional problem. A claim can be stated in a way that is not clear, leading to confusion. Basically there are two types of claims:

- The ''typical'' data claim – Half of the customers are expected to observe better performance and the other half worse performance. With statistical tests, one can determine whether observed performance is consistent with the manufacturer or unreasonably far from the claim.
- The ''warranty'' claim – Here, all customers are guaranteed performance better than the limit. If customers don't achieve this level, they are told to contact the service department.

The advantage of using the first method is that claims will appear better, e.g. typical precision 3% coefficient

of variation (CV) instead of less than 5% CV. The disadvantage is that for a customer to verify performance, statistical tests must be conducted. From a manufacturer's standpoint, this can lead to complaint calls that are not real. The second method is easier for both the customer and manufacturer but requires understanding that a claim stated this way does not look as good as stated in the first method (although in reality they are representing the same performance).

8.1.1 Pass–Fail Limits vs Continuous Quality Improvement

Manufacturers, like mostly everyone, are faced with yes–no decisions. Should we release or not release the product (meaning has it met or not met its goals)? However, consider two assays, where assay A is just inside and assay B is just outside specification. From a manufacturer's standpoint, assay A has full value (i.e. identical with an assay that is perfect) whereas assay B has zero value. From a customer standpoint (assuming that the customer could observe performance from the assay that failed the manufacturer's specification), the two assays have similar performance (and value). Yet manufacturers must still treat these two assays, that have similar value to a customer, as either having full or zero value.

There is no easy way to deal with this problem. What happens in practice is that the yes–no region, while conceptually clear (i.e. accept if precision is $\leq$4.0% CV, reject if >4.0% CV) becomes fuzzy: accept if precision $\leq$4.0% CV; conduct further discussions if precision is between 4.0 and 5.0% CV; and reject if precision is >5.0% CV. Thus, targets set at the beginning of a project are revisited throughout the project development cycle and especially near product release. Since many specifications are set close to the technical capability of a system (owing to competitive pressures), the situation occurs frequently.

8.2 Regulatory Requirements

While not having the same scrutiny or oversight as required for new drugs, new medical devices require (with different levels of effort depending on the device) regulatory approval in most countries. Assays that are most regulated are tumor markers and infectious diseases. FDA approval of these assays requires a substantial effort. Instrument systems also require a variety of approvals related to safety or demonstration of lack of interference to other electronic equipment. Medical device manufacturers have become International Organization for Standardization (ISO) certified. In the USA, regulation continues after product launch at both the manufacturer and the customer site. Manufacturers are periodically inspected by the FDA. If problems arise, warnings letters are issued with product recall a possibility. Medical device reporting is a regulation aimed at getting manufacturers to report any possible threat to patient safety due to use of the device (e.g. whether or not they have actually occurred). Hospital laboratories are routinely inspected by accreditation groups.

8.3 Product Support Strategies

Service strategies can play an important role in a company's overall strategy, since customer contact with a company's service department can affect the customer's level of satisfaction and affect future buying decisions. Often this contact occurs when the customer is frustrated. Surveys devoted to assessing customer satisfaction with manufacturers are often a measure of satisfaction with service rather than a measure of the customer's regard for the product itself.

An example of a service strategy follows – but includes required items outside the service group's control. Thus, the service strategy must be built into product development. The key elements are:

- a diagnostic strategy for instruments;
- a means to assess an instrument's status remotely;
- a means to correct faults.

Complex medical instruments require a diagnostic strategy consisting of sensors to record key measures in each subsystem. What needs to be measured is developed from fault trees and a failure mode effect and criticality of action (FMECA). This analysis also dictates how the software will respond when measured values are outside of limits. Measurement results are stored in a database that can be accessed for trend analysis.

Trends need to be monitored not only on the instrument in question but across all instruments. This is facilitated in a variety of ways. If the instrument has a modem, the database can be queried remotely. The Internet can also be used, provided that the instrument is on a network. Remote monitoring can be a two-way communication so that if a fault is detected that requires customer action, the customer can be notified remotely about what action to take.

ABBREVIATIONS AND ACRONYMS

AMSAA	Army Material Systems Analysis Activity
CV	Coefficient of Variation

DFA	Design for Assembly
FDA	Food and Drug Administration
FMECA	Failure Mode Effect and Criticality of Action
FRACAS	Failure Review Analysis and Corrective Action System
hCG	Human Chorionic Gonadotropin
HCV	Hepatitis C Virus
ISO	International Organization for Standardization
IVD	In-vitro Diagnostic
LDH	Lactate Dehydrogenase
NADH	Nicotinamide Adenine Dinucleotide (Reduced Form)
NCCLS	National Committee for Clinical Laboratory Standards
NPV	Net Present Value
QFD	Quality Function Deployment
R&D	Research and Development
TAAF	Test, Analyze and Fix

Plasma contains a large number of different proteins with varying structural characteristics. The ''plasma proteins'' have been defined on the basis of plasma concentration and amenability to measurement in certain types of measurement systems. In the past, they were proteins present with concentrations above 0.05 g L^{-1}, but more recently detection limits have been decreased to about 0.001 g L^{-1}. However, the group of proteins is not defined on a pathophysiological basis and the definition remains idiosyncratic and incomprehensible to the noncognoscenti. The function of an increasing proportion of them is known and the evidence suggests that they are present either with a specific role in the plasma or that they represent cellular proteins shed into the circulation as a result of degradative processes. Many plasma proteins show characteristic changes in concentration or structure either resulting from genetic dictates that may give rise to disease directly or as a result of changes reflecting pathological or physiological processes. All the transcellular fluids, such as cerebrospinal fluid (CSF), urine, synovial fluid and saliva, contain most or all of the plasma proteins, but there are some additional proteins secreted specifically into these fluids.

This chapter reviews the many methods applied to proteins for clinical and research purposes. Also addressed are the pitfalls not often appreciated by the worker presented with a sample to be analyzed in an increasingly impenetrable ''machine''.

1 INTRODUCTION

Proteins are integral to life as we know it; not only are they the building blocks of carbon-based organisms but they act as catalysts, signaling and controlling molecules for metabolism. Thus, it is not surprising that interest in proteins has assumed a logarithmic growth pattern with no signs of abating. The introduction of DNA techniques that allow the identification of the underlying genetic basis of defects, the development of recombinant methods to produce mass quantities of what once were vanishingly small amounts of purified native proteins, and the creation of immunological analyses that precisely measure many proteins from microliter-sized samples have brought us to a level of scientific sophistication that exceeds our ability to interpret the results.

Many of the seminal publications about proteins and the methods to examine them date back to the 1960s and 1970s. These broadly informative texts are increasingly difficult to locate except in the most extensive libraries. Nevertheless, they are listed here as complete sources on this topic. This area of methodological study is essentially matured and well accepted. The application to clinical medicine, however, is in its infancy.

1.1 Definition of "Protein"

The word protein refers to organic substances that are chains of amino acids, in association with a wide variety of other moieties including carbohydrates, lipids, mucins, metals and other inorganic molecules.[1,2] A constant feature is that they are primarily the product of living organisms and are coded for in the genome. In recent years they are also the product of synthetic processes whereby proteins, unlike any seen in nature, are produced. The potential is enormous, but concerns about the safety of such xenobiotic materials is mounting in public awareness.

The basic unit of protein is the amino acid, of which there are about 20. These small molecules are assembled into peptides, then polypeptides and then into macropolypeptides or proteins. This name is apt because even the smallest protein has a molecular mass (M_r) in excess of 15 kDa.

The general formula for an amino acid fits the structure of $CH(NH_2)COOH$ associated with various side chains usually denoted R to produce $R{-}CH(NH_2)COOH$. All the amino acids participating in protein building are α-amino acids with the same structural backbone, with the exception of proline, which contains an imino ($-NH-$) instead of an amino ($-NH_2-$) group. At its most basic, a peptide is the linkage of two or more amino acids between amino and carboxyl groups ($-NH_2$, $-COOH$, respectively) to form repeating chains in excess of 100 units. Living organisms are composed of different forms of amino acids connected together, end to end, in various combinations along with sugar side chains. This level of organization is referred to as the primary structure because it is a scaffolding held together by covalent bonds.

Amino acids connect together in a linear chain whose regularity is interrupted only at the site of proline molecules, which create a deviation in the direction of the chain. Secondary structure results from the association of molecules in the chain, adding complexity to the simple chain and side-chain structure. The arrangement of the chain, often as a helical structure, is held in a relatively firm position by the formation of hydrogen bonds between hydrogen atoms of one amino acid and oxygen atoms of another. The secondary structure does not account for the compactness of proteins in nature. The coiled peptide chains are packed together in the protein molecule in complex ways to form sheets or globular masses held together by intra-chain bonds, often due to the formation of covalent disulfide bridges between cysteine residues. This physical arrangement, known as the tertiary structure, dictates the shape, function, and ultimately how the protein is viewed as the target of the immune system of living multicellular organisms. It also dictates the chemical response of simpler organisms to polypeptides and proteins in their external environment.

Because all life as we know it has evolved in an aqueous environment, the response to water molecules is paramount. Hydrophobic molecules repel water and are often lipid in nature, whereas hydrophilic molecules respond positively toward water molecules. Both are crucial to life and permit cells to contain high-energy lipid within aqueous cell structures. Hydrophobicity is the result of amino acid side chains that are insoluble in water, whereas hydrophilic proteins have side chains that readily form hydrogen bonds with water molecules. This feature, characteristic of each protein, is promoted by the location of the side chains in the protein structure. Hydrophobic peptides are generally oriented such that the water-repelling side chains are in the core of the folded molecule, whereas hydrophilic units are oriented towards the exterior. Many large protein molecules contain both -philic and -phobic aspects, a feature that allows for such basic features as stable cells in an aqueous medium – the plasma – and retaining fat stores in an accessible form with controlled mobilization.

The classification of proteins can present a bewildering scheme often combining every feature of a known protein. Classification can begin with molecular mass, shape, function, simple or complex, and with what prosthetic group(s) they are associated. In fact, every protein can be classified by all techniques, depending on the view of the classifier. Additional schemes of classification reflect functions of the basic structural components, the isoelectric point (pI), sieving properties, affinity for various materials, including ligands, thermal and acid stability, and solubility, to name but a few.

Finally, the primary amino acid sequence of all proteins is determined by a given DNA nucleotide sequence in living cells. The production of a species of protein is the result of transcription of a unique sequence from DNA to complementary sequences of RNA, which then act as a template for assembling the amino acid sequences from available cellular substrates – amino acids. Post-transcriptional modification within the Golgi apparatus proceeds to prune portions from the original sequence or to add carbohydrates or lipids, thus conferring function, unique immunogenicities and physicochemical properties.

It can be appreciated that with such a complex structure, so variable an assembly line and the enormous opportunity for mutational change with each cell division, the family of proteins is almost limitless and constantly under pressure for change, good or bad. It is at this point that the most sensitive mechanism of all comes into play: the ability of the immune system of higher animals to discriminate between minor structural differences, at primary, secondary or tertiary levels. As a result, protein chemistry relies heavily on immunochemical methods for qualitative and quantitative analysis, the description

of constituent units and even the study of phylogenetic origins of today's family members.

1.2 Definition as it Applies to "Serum" Proteins

Limiting this section to serum proteins[3] (or, more correctly, plasm proteins) simplifies the discussion to a degree, although as methods become increasingly sensitive the line between insoluble structural proteins and those in the serum becomes blurred, resulting in the inclusion of a greater number of different proteins (Table 1). The process whereby plasma becomes serum is complex and results in a variety of changes to several proteins in the plasma. Plasma, the liquid phase that circulates in our vessels, becomes serum in vitro if it is allowed to "clot". The change is the conversion of the plasma protein fibrinogen to an insoluble meshwork of fibrin. This does occur in vivo at sites of injury or blood accumulation in tissue spaces, and is the mechanism of homeostasis.

The result of complete clotting is the disappearance of fibrinogen as it polymerizes and comes out of solution. The cleavage of a small end piece of the long yet soluble molecule allows cross-linkage to occur, but remaining in solution are the cleaved pieces, the fibrin split-products. As normal clot resolution proceeds, nonclottable sections of fibrin circulate and can be measured as evidence of clot destruction.

The process of clotting also has significant effects on other plasma proteins. The process activates proteolytic enzymes, which alter other clotting factors as well as proteins not involved in clot formation. In vivo, the meshwork of the protein clot acts as the scaffolding into which the cells of repair migrate. Serum is therefore the end product of the enzymatically induced process that produces a clot; it is a structure that, because of the physical actions of the mesh-like molecules, contracts, trapping cellular elements and expressing the aqueous phase for our examination and discussion.

2 HISTORY

The awareness that there was such a material as protein developed in the mid-1800s. Berzelius coined the term "protein" meaning "of first rank" (in biological importance) in 1838. The methods available were rudimentary and the reduction of the broadly defined material to subspecies required years and new methods.

Table 1 Clinically useful serum proteins

Acid phosphatase	Chymotrypsin	Intrinsic factor
Alanine aminotransferase	C-Reactive protein	Lactic dehydrogenase
Albumin	Creatine kinase	Lysozyme
Alkaline phosphatase	Elastase	Lactoferrin
Amylase	Factor II	Leukocyte alkaline phosphatase
α_1-Lipoprotein	Factor V	Lipoprotein(*a*)
α_1-Fetoprotein	Factor VIII	Melanocyte-stimulating hormone
α_1-Microglobulin	Factor X	Myoglobin
α_1-Antichymotrypsin	Factor XI	Orosomucoid
α_1-Antitrypsin	Ferritin	Parathormone
α_1-Antithrombin III	Fetuin	Procalcitonin
α_2-Macroglobulin	Fibrinogen	Proinsulin
β_2-Glycoprotein 1	Fibronectin	Prolactin
β_2-Lipoprotein	Follicle-stimulating hormone	Prostatic acid phosphatase
β_2-Microglobulin	γ-Glutamyl transferase	Prostate-specific antigen
β_{1h}-Globulin	Glucagon	Prothrombin
C1-Esterase inhibitor	Growth hormone	Renin
C1q	Haptoglobin	Retinol-binding protein
C1r	Chorionic gonadotropin	Serum amyloid A protein
C1s	Hemoglobins	Thyroglobulin
C2	Hemopexin	Thyroid-stimulating hormone
C3	IgA	Tissue transglutaminase
C4	IgD	Transferrin
C5	IgE	Transthyretin
Calmodulin	IgG	Troponin
Cathepsin-G	IgM	Trypsin
Carcinoembrionic antigen	Insulin	Tumor necrosis factor α
Ceruloplasmin	Interleukin-1	Tumor necrosis factor γ
Cholinesterase	Interleukin-6	Vitamin D-binding protein

IgA, immunoglobulin A; IgD, immunoglobulin D; IgE, immunoglobulin E; IgG, immunoglobulin G; IgM, immunoglobulin M.

Thus in 1861 Graham described dialysis as a means of separating proteins (colloids) from crystalloids. In 1862, Schmidt showed that some proteins, the globulins as he called them, were insoluble in water. Analyses were also extremely simple, often relying on visual color changes upon reaction with various reagents. Early in the 20th century it was recognized that if materials containing proteins were injected into animals, those animals produced a substance that had considerable specificity for the injected material, especially microorganisms. It was in 1890 that Emil Von Behring showed that this antibody, as it was called, resided in a chemically definable fraction of the plasma proteins. He received the Nobel Prize in 1901 for this discovery.[4] Thus the concept of specific immune reactions was formed. Soon it was noted that these ''specific'' antisera produced a visible precipitate when they were mixed with the immunizing material, especially a specific species of bacteria. This flocculation of microorganisms became the basis for estimating bacteria of the type that stimulated the antiserum from others that were considered to be different. Visual assessment of the intensity of flocculation became an estimate of potency when antisera were being considered for therapeutic uses.

When antisera were allowed to react in a transparent medium such as the agar used for bacterial culture, it was noted that the precipitate was comparable to that seen in the test tube. This precipitin technique advanced the knowledge of specificity greatly and has been carried to amazing degrees in the form of immunoprecipitin analysis. The nuances of antigenic identity were explored intensely in the 1960s and 1970s. The next step was to replace the agar medium with agarose, which had less reaction with proteins. Two additional steps were required: the development of a synthetic medium, polyacrylamide, whose interstices could be adjusted at will; and the development of immunofixation and immunoblotting, which allowed the immunological identification of proteins separated on electrophoretic media. This remains a prime analytical technique, revealing that many polymorphisms exist and that minor changes in structure often produce different banding patterns.

Of great interest was the fact that proteins could be eluted from gels, after separation, and then used to immunize animals. Not surprisingly, these apparently ''pure'' proteins often produced antisera with multiple specificities. The reasons are the same as for less sophisticated and imprecise separations; the animal's immune system detects differences that the original separation technique cannot. As we will see later, by repeating this process in various media and buffers, apparently pure materials can be reduced further to extreme purity.

An intermediate step in protein purification came with the immunization of an animal with an antigen/homologous antibody complex that produced an even more superior product. Yet again, contaminants remained that at the time caused no difficulty because of the low sensitivity of the methods then in use. The ultimate method is to produce recombinant proteins by the insertion of the specific gene for the protein into a microorganism, insect or plant and more recently into cloned mammals. These proteins can be harvested from their serum or even from their milk.

3 PHYSIOLOGY AND PATHOPHYSIOLOGY

In general, proteins are synthesized at controlled rates during health with measured levels falling within an expected reference range according to age and gender.[1,5,6] This can be viewed as evidence of relative homeostasis. As will be described in more detail below, the assessment of a steady state cannot be made by examining one protein in isolation. However, for the sake of simplicity, a single serum protein level that falls outside the reference range is cause for concern. If the value is above or below normal, the synthetic rate may be depressed or increased, or catabolism altered. The protein may be lost to some other space or consumed by a process that removes it from the circulation. This occurs during immune complex diseases where complement levels fall precipitously, not by destruction but by sequestration onto and into tissue surfaces. Less common is an inability to synthesize normal levels for some genetic reason. The differences between serum and plasma have been described above.

From a practical point of view, however, the blood proteins that are measured most often are largely unaffected and will give the same results in either plasma or serum. However, dilution and mixing of plasma with aqueous fluids, especially those containing antisera, can trigger the clotting reaction in the cuvettes and tubes of the instrument, leading to error in volume transfer, contamination, and all too often complete failure of the system. Thus, plasma is not the ideal fluid for today's automated devices, whereas it could easily be used in manual methods such as in-gel techniques. Therefore, most analyses now use serum and despite the usage of the word plasma, serum is understood. There are exceptions, of course. Virtually all assays of the clotting system require plasma, but again in some instances serum is preferred.

3.1 Synthesis

The liver is a major site of plasma protein synthesis, although some proteins synthesized there are also produced in peripheral tissues[3] (Figure 1). The other major alternative sites of plasma protein synthesis are

Figure 1 Diagrammatic representation of protein metabolism exemplified by albumin quantities in a 70-kg individual. (Adapted from J. Whicher, C. Spence, *Ann. Clin. Biochem.*, **24**, 572–580 (1987).)

the cells of the immune system. Thus, we know that immunoglobulins are only synthesized by B-cells whereas cell-surface proteins such as β_2-microglobulin are made by many different cells.

The mechanism of protein synthesis is common to all cells. In the cell, proteins are transcribed onto messenger RNA, which is usually translated on cytoplasmic polyribosomes, whereas proteins destined for the cell membrane or for secretion are translated on the membrane-bound ribosomes of the rough endoplasmic reticulum. After synthesis, many proteins possess two additional peptides at the N-terminus. A hydrophobic prepeptide acts as a ''leader'', directing the molecule through the membrane of the endoplasmic reticulum. This is cleaved almost immediately on leaving the protein with a propeptide, which is not removed until maturation occurs in the Golgi vesicles or in storage granules immediately prior to secretion. Glycoproteins have carbohydrate residues added by sugar transferases in the lumen of the endoplasmic reticulum and these may control folding of the polypeptide chain and act as recognition sites for subsequent metabolism. Control of protein synthesis may be exerted on the rate of transcription of messenger RNA from DNA or at the level of translation.

Factors affecting plasma protein synthesis have been studied in the liver. Many factors influence hepatic plasma protein synthesis from specific regulatory factors to amino acid availability. Toxic factors such as ethanol may inhibit synthesis, and hormones have an important, but complex effect. In clinical practice, the effects of androgens and estrogens are the most important. The synthesis of several proteins by the liver is increased in protein-losing states when the plasma albumin level is decreased.

Specific regulatory mechanisms are also being increasingly recognized. It is notable that the synthesis of acute-phase proteins, most of which have specific functions in the inflammatory reaction, are increased within the liver during inflammation in distant tissues due to the action of cytokines released by certain specific cells of the immune system.

3.2 Distribution

Intracellular proteins reach the intravascular space either by secretion or release as the cellular envelope is ruptured or becomes permeable to proteins due to osmotic or metabolic stresses, or as the result of cell turnover and renewal.[3] Regardless of the circumstance, intracellular proteins are often released into the circulation where they can be measured. In this way increased levels of intracellular proteins can signal increased cell turnover or death. This can be seen with tumor markers where measurements afford an exquisitely sensitive means of monitoring tumors that have a propensity to release intracellular proteins. Testicular tumor release of α_1-fetoprotein (AFP), normally absent in normal male serum (it is a normal constituent of the fetal yolk-sac and liver, and during pregnancy), is a good example. Today many people are alive and tumor-free as the result of very early detection of increasing levels of AFP by microscopic metastases and the institution of treatment long before any other sign of tumor recurrence is evident.

All plasma proteins can be found in virtually all spaces within the body, whether they are completely surrounded by intact membranes, such as the intravascular spaces, spinal fluid spaces or contents of the gestational sac, or connecting to the exterior of the body, such as the bronchial tree, urinary bladder or segments of gastrointestinal tract. For smaller plasma proteins the total mass is greater in the extravascular spaces than within the vascular tree, whereas for large proteins the mass within the vascular spaces is usually greater. In practice, the concentration ratio between serum and urine levels or spinal fluid levels can be very informative.

Proteins may be lost into extravascular spaces, e.g. the abdominal or pleural space, when disease results in *transudation* or *exudation* of protein-rich fluids, each with characteristic features (see Table 2).[7] Ascites – the accumulation of a serum-like fluid in the abdominal cavity in cirrhosis or malignancy – can be astonishing; at times, 5 L or more can be present.

Less often, at least in the Western world, are third spaces that are the result of parasitic cysts, which can be enormous, or the accumulation of abdominal fluid as the result of severe nutritional deficiencies. In the same parts of the world, afflicted persons can accumulate enormous quantities of tissue fluid representing a major fraction of

Table 2 Characterization of effusions

	Transudates	Exudates
Appearance	Clear, straw-colored	Clear, turbid, bloody
Specific gravity	<1.015	>1.015
Protein concentration	$<30\,g\,L^{-1}$	$>30\,g\,L^{-1}$
Effusion/serum total protein	<0.5	>0.5
Lactate dehydrogenase concentration	$200\,IU\,L^{-1}$ or 2/3 normal level	$>200\,IU\,L^{-1}$ or >2/3 normal level
Effusion/serum lactate dehydrogenase	<0.6	>0.6
Serum/ascites albumin	>1.1	<1.1
Glucose concentration	Equal to serum	<Serum level
Leukocyte count	$<1000\,mL^{-1}$	$>1000\,mL^{-1}$
Etiology	Noninflammatory Remote systemic disease Plasma ultrafiltrate	Inflammatory Local disease Altered vascular permeability

Reproduced with permission from Ritchie and Navolotskaia.[7]

the total body fluids. These devastating illnesses result from parasitic infestations that block the normal return of protein-rich lymphatic fluids to the general circulation, with resultant massive edema of the lower extremities.

Protein can be lost in tremendous amounts to the exterior through extensive burns, damaged intestinal surfaces or through the genito-urinary tract in the nephrotic syndrome.

The protein content of these sequestered or ''discarded'' fluids varies with the primary process and the type of epithelium that lines the surfaces. Fluid collected in a distended gall bladder will have a different profile from fluid that collects nearby in a pancreatic cyst or outpouchings of the bowel (Meckle's diverticulum). In some cases, study of the characteristics of the fluids can give a precise explanation about the cause: e.g. whether it is a tumor or not and what type of malignancy is responsible.

Plasma proteins pass continuously from the vascular to the extravascular space and as much protein destruction takes place in the capillaries as in the extravascular spaces. There is a concentration gradient between the plasma and the extravascular fluid. The passage across capillary walls is both through interendothelial junctions (especially in the choroid plexus of the central nervous system) and by pinocytic transport across endothelial cells. In both cases, proteins must pass across the basement membrane. It is probable that some of the pinocytic vesicles fuse with lysosomes, resulting in enzymatic degradation of the contents. It is in this way that many plasma proteins are catabolized by the capillary endothelium. The protein content of the transcellular fluids and extracellular fluid is thus dictated by a combination of these two nonspecific mechanisms as well as by specific transport mechanisms. In all such fluids, low-molecular-mass proteins predominate, owing to the molecular sieving effect of the capillary basement membrane. It is important to appreciate that the protein content of transudates will vary from tissue to tissue according to the nature of the capillary interendothelial junctions, and also that the fluid, once formed, is rapidly altered by subsequent metabolic processes. For example, the protein content of bladder urine is very different from that of the glomerular filtrate owing to the reabsorption of proteins in the proximal tubule. Ventricular CSF is very different from lumbar CSF due to the progressive equilibration of the fluid with plasma during its passage down the spinal column.[7] The effect of changes in posture in altering the concentration of proteins in plasma is also of practical importance.

3.3 Catabolism

Plasma protein breakdown probably occurs to a greater or lesser extent in most cells of the body, and degraded plasma proteins provide an important source of amino acids for cellular protein synthesis and tissue repair.[3] In particular, degradation occurs in the capillary endothelial cell during the process of pinocytic transfer from lumen to basement membrane. Proteins that have passed through the endothelium may then be catabolized by the tissue cells they come into contact with, again by pinocytosis and lysosomal degradation.

The liver is also important in protein catabolism. The hepatic sinusoids lack a continuous basement membrane, the endothelial cells have marked intercellular fenestrations and the pericapillary cellular covering is far from complete so that the space of Disse and hepatic sinusoids form a single mixing pool for proteins. Plasma proteins thus enter and leave the hepatocyte without hindrance. This, of course, explains why high-molecular-weight proteins and particles synthesized in liver cells, such as α_2-macroglobulin (725 kDa) and very low-density lipoprotein (VLDL) (512 kDa), enter plasma. Most plasma proteins are glycoproteins and the carbohydrate side chains may have a key role in controlling degradation. Desialation of many glycoproteins results in increased catabolism and it is possible that an intact carbohydrate moiety protects circulating proteins from hepatic catabolism. Removal of these residues as a result of the action of circulating or membrane-bound enzymes may act as the catabolism-initiating process for binding of proteins to hepatocyte membrane receptors, with subsequent pinocytosis and intracellular degradation by

lysosomal enzymes. It is possible that other molecular changes such as polymerization or complex formation may also act as catabolism initiators.

The kidney is the site of breakdown of low-molecular-weight proteins such as immunoglobulin light chains. Between 2 and 4 g of plasma protein are filtered by the glomerular capillaries each day, but only about 100 mg day^{-1} appear in the urine. Proteins pass through the glomerular filter in inverse proportion to their molecular size and are largely reabsorbed in the proximal tubule by pinocytosis and degraded by lysosomal enzymes. Pinocytosis by tubular cells is probably competitive and there may be selective mechanisms for some types of proteins.

3.4 Function

A functional classification of plasma proteins is useful in understanding the changes that occur in disease because proteins of related function often form interacting systems (e.g. immunoglobulins and the complement system). It is probable that most of the plasma proteins present at relatively high concentrations in the blood have a functional role in circulating blood, but it is equally clear that many of those present in trace amounts represent cell-surface or intracellular proteins that have been shed into the bloodstream.[1] Protein function is usually the consequence of secondary and tertiary structure and whether or not they are hydrophobic or hydrophilic.

3.4.1 Transport

Plasma proteins are concerned with the transport of a wide range of substances from the site of production to their site either of action or of catabolism. Another important aspect of their role is the maintenance of a pool of biologically inactive substance in equilibrium with the pool of free active substance. The carrier proteins may have a complex role in the metabolism of the molecules with which they are associated, such as interacting with enzymes or cellular receptors. Transport proteins perform just as one would expect: a moiety is picked up and transported to a target location, where it is released for further use. The divested protein may be free to be reloaded and to transport the same species of moiety again or it may be destroyed after entry into the cell. Serum transferrin is such a protein that interacts with a specific cell-surface receptor to take up and deliver iron. The apoprotein apotransferrin picks up one Fe^{3+} binding to one of the two binding sites. Full saturation of transferrin does not occur, with the average value falling to ca. 1.25 iron atoms per average molecule. Iron is usually bound near the gut mucosal surfaces and is primarily transported to the bone marrow where the iron is transferred to hemoglobin in immature red blood cells: the reticulocytes. It may also transport the iron to the liver cells where ferritin is the intracellular receptacle for iron storage. In hereditary hemochromatosis, ferritin levels rise greatly as a result of leakage from within the cells. By contrast, haptoglobin provides a one-way transport of hemoglobins from wherever red cells are broken down, binding it firmly and then transporting it to the liver where the iron is transferred to ferritin. The heme portion is then released and degraded to biliverdin in the hepatocytes and released into the bile canaliculae, where it is ultimately streamed to the gut and eliminated as bilirubin. Haptoglobin is a suicidal protein, whereas transferrin is a true transport protein. Some protein species have a sharply limited function, such as to bind to a single hormone. Transthyretin is an unusual protein in that it carries two receptors: one site for retinol-binding protein, itself a transport protein for vitamin A; and two sites for thyroid hormones T3 or T4.

Transport of small molecules is also an important function of certain proteins. Albumin, for example, the plasma protein in highest concentration, acts to bind and transport drugs from points of entry to sites of use, preventing rapid loss through the kidney because of their relatively small size. It also provides the constantly available source of amino acids for tissue repair. The amino acid building blocks are derived from the albumin molecules themselves, so it also has a suicidal aspect. In addition to binding drugs, which can have significant effect on the bio- and physicochemical characteristics of albumin, endogenous materials such as bilirubin can act in the same manner. Albumin also acts as a reservoir for bound molecules in equilibrium with the free substance; calcium is such an example.

The binding characteristic of albumin for small molecules such as pigments and dyes is the basis for the more common methods of analysis. Prior binding to endogenous pigments can alter the dye-binding ability of albumin during analysis. As a result, measured values for albumin may be decreased falsely in the serum of patients with high levels of bilirubin or certain drugs such as penicillin. The immunochemical methods, on the other hand, are not affected by dye binding and are gaining favor as the method of choice in those laboratories where immunochemical methods are available.

3.4.2 Proteins of the Immune System

Immunoglobulins provide the adaptive immune response of higher animals for the elimination of foreign antigens or altered autoantigens. Complement proteins provide both effector mechanisms for antibody and an additional nonadaptive defense mechanism. The unique serum protein C-reactive protein may represent a primitive, nonadaptive mechanism-activating complement.

3.4.3 Proteins Associated with the Acute-phase Response

A number of plasma proteins increase in concentration during inflammation in many tissues. The so-called ''acute-phase response'' represents the switching on – by specific messengers, cytokines – of synthetic mechanisms for proteins that are involved in the inflammatory process as mediators, participants or inhibitors.

3.4.4 Signal Proteins

Many plasma proteins are messengers. Most of the classical protein hormones are present at low concentrations, but some, such as human placental lactogen and the placental protein Sp I, are present at high enough concentrations to have been classed as plasma proteins.

3.4.5 Proteins of Blood Clotting

The interacting proteins of the blood clotting system form a quantitatively important group of plasma proteins. The inhibitors and active proteolytic enzymes of this system interact closely with the complement and kallikrein–kinin systems, and thus with inflammation.

3.4.6 Tissue-derived Proteins and Oncofetal Proteins

Some of the proteins present in low concentrations in plasma are cell-membrane proteins shed into the blood during cell-membrane turnover or as a result of cell death. A number of other trace proteins, the oncofetal proteins, are produced by tumors as a result of depression of genes coding for fetal proteins or proteins not normally produced by the tissue of origin or the tumor.

As a first step to viewing blood proteins in an organized fashion, Table 3 categorizes a few of them. Not surprisingly with such a diverse and complex family of molecules, some proteins will have multiple functions and others will have overlapping or redundant functions and be essentially back-up systems.

4 METHODS

Serum proteins have become commodities of research, commercial, diagnostic and therapeutic interest.[8,9] The tremendous leaps in technology and understanding have made individual species of this family big business. A myriad of companies have sprung up around the globe with serum proteins as their principal, if not sole, product. The technological advances, a product of both sponsored and commercial research, have brought this discipline to what will likely be an ever-expanding source of improvement in all fields from medicine to the environment.[5] Because the title of this article focuses our attention on proteins found in serum, our scope is limited. Developments in agriculture, food science and the chemical industry are dealt with by other articles in this Encyclopedia.

The developments in serum protein science fall primarily into two categories: those measured in human or experimental animal serum; and those derived from the serum of animals whose proteins (antibodies) are used in diagnostics or therapeutics. In other words: those proteins to be analyzed and those proteins performing the analyses.

4.1 Immunological Reagents

Measurement of proteins is basically separated into two classes: those that rely on the use of antibodies to target the analyte; and those that separate the protein from, or in, its original matrix for analysis by chemical or physical means. Listed in Table 4 are the characteristics of proteins that can be used either to describe the amounts present or to describe qualitative features. Most methods used today are for medical, veterinary, agricultural or microbiological applications for diagnosis, monitoring or prognostication. In addition, protein analysis forms an integral tool for all biological research. Most methods, for purely economic reasons, analyze proteins in the milieu

Table 3 Classes of serum proteins and a few examples

Transport/storage	Protective	Enzymes	Inhibitors
Albumin	α_1-Fetoprotein	Acid phosphatase	α_1-Antitrypsin
Ceruloplasmin	Chemokines	Alkaline phosphatase	α_1-Antichymotrypsin
Ferritin	Clotting factors	Chymotrypsin	α_2-Macroglobulin
Haptoglobin	Complement series	Creatine kinase	α_2-Antiplasmin
Hemoglobins/myoglobin	C-Reactive protein	Elastase	Antithrombin III
Hemopexin	Fibrinogen	γ-Transglutaminase	C1-Esterase inhibitor
Lipoproteins	Immunoglobulins	Leukocyte alkaline phosphatase	
Orosomucoid	Mucoproteins	Lecethin-cholesterol acyltransferase	
Retinol-binding protein		Plasmin	
Transferrin		Thrombin	
Transthyretin		Tissue transglutaminase	
Vitamin D-binding protein		Trypsin	

Table 4 Methods of protein measurement

Focus of method	Mode of results
Antigenic specificity	Quantitative or qualitative analysis
Antibody activity (for immunoglobulins)	Quantitative or qualitative analysis
Associated moieties	Measurement of metal, lipid or carbohydrate
Electrophoretic mobility	Measure p*I*
Enzyme sensitivity	Cleavage with proteolytic enzymes and measured effect
Function	Enzymatic, ligand, immunospecificity (for immunoglobulins)
Molecular configuration	Stoichiometry
Molecular mass	Ultracentrifugation
Molecular shape	Rotational polarimetry
Molecular size	Sieving electrophoresis
Thermolability	Visible or measurable effect on physical status or function

of the original sample to avoid the inevitable increased cost of separation. Unless the examination is of a general nature, e.g. total protein, or addresses a feature that allows a specific protein to be examined in the presence of a large number of surrounding proteins, e.g. enzyme activity, the methods of analysis require the application of a specific antiserum: immunoanalysis. As this is such a fundamental and complex issue, it will be dealt with first.

4.1.1 Antiserum Production

Antisera are animal immunoglobulins, either raised in intact animals or produced in vitro from clones of antibody-producing cells taken from immunized animals. The fundamental difference between these is that an animal immunized against a macromolecular protein antigen will produce many thousand antibody species reacting with a large number of antigenic determinants on the protein. Monoclonal antibodies, produced from clones of plasma cells grown in vitro, will react with only a single antigenic determinant per protein molecule unless this determinant is repeated in the protein structure. The characteristics of antibodies that are important in immunoanalysis are the avidity, affinity and titer. The avidity is the binding constant of a homogeneous species of antibody to a single antigenic determinant. It is a theoretical concept except in the case of monoclonal antibodies. The affinity is the average binding constant of all the antibody molecules in an antiserum to all the relevant antigenic sites on the target protein and is a characteristic of great importance because it determines the speed of reaction with antigen and the stability of the immune complexes formed. The titer is the concentration of reactive antibodies in the antiserum. The titer can be modified by methods of concentration of immunoglobulin in the antiserum and the affinity can be modified by immunoabsorbtion techniques to concentrate antibody molecules of high avidity and reject those with low affinity (see below). The preparation of specific antisera requires that the protein antigen, the analyte, be isolated from the best available source. Recent regulation requires that the source be shown not to contain infectious agents such as the human immunodeficiency virus and hepatitis B virus. For this reason, source materials from acceptable individual donors have become extremely valuable. In recent years the intermediate step, largely avoiding problems of purification of the starting antigen and also the removal of contaminating specificities from the animal product, has been the production of recombinant antigens; this subject is not addressed in this article. Preparation of the desired immunogen has become more sophisticated, partly because of improved techniques and partly through the realization that the higher the purity of the administered antigen, the more efficient the process of removing contaminating specificities from the antiserum by immunoadsorption.

In the early years of antiserum production it was not unheard of to immunize an animal with a very impure preparation extracted from a serum or tissue believed to have the antigen in high concentration and then to absorb the product with a serum or crude material that was devoid of the desired protein. For example, animals were immunized with crude preparations of serum from small fetuses with high levels of α-fetoprotein. The harvested antiserum was predominantly against contaminants and the specific anti-α-fetoprotein was only a small fraction of the total. To remove this large amount of interfering antibody, whole normal male plasma was added until no further precipitate occurred. Although extremely crude, the method did provide usable antisera. To this day the same problems exist. The purest of immunogens are shown by the immunized animal to be laced with contaminants. Not infrequently, the trace contaminants can be far more immunogenic than the target immunogen.

A further advance in the preparation of high-quality antisera was the development at the Catholic University of Louvain, Belgium by Masson and his associates Mancini and Carbonara of the method of immunizing with low microgram doses of immunogen, injected intracutaneously into multiple sites on the back of the animal, usually a goat.

The antigenicity of the injected material is usually enhanced by emulsification with a lipid-rich material, of which there are several. In the main, whatever material is added, whether mineral oil or tubercle wax D or synthetic adjuvants, the result is an intense inflammatory response with the production of cytokines, such as interleukin-6, which enhance the immune response at the sites. Subsequent booster doses in the same manner are required to elevate the titer of the antibody to the desired

levels. One method of interest was immunization with a washed precipitate produced by an antiserum that was as pure as could be obtained with its respective antigen. The precipitates were developed in relatively dilute solution to avoid the problem of ''occluded'' protein: those that become trapped in the mesh of developing antigen–antibody precipitates. The approach did, in fact, improve the quality in some cases. Another modality is to immunize animals with the fixed and stained proteins separated in polyacrylamide gels. The bands are sliced from the slab, emulsified and injected. Despite fixation and staining, intact antigenic determinants remain.

The inevitable requirement for removal of contaminating antibodies also evolved with time. Initially, soluble antigen was added to the antiserum and the precipitated contaminants were removed by centrifugation. However, as antiserum performance became more demanding, the possibility of inserting unwanted reactants into the finished product and the inevitable dilution by the absorbing solution forced workers to develop efficient adsorptive protocols. Ultimately, large columns of absorbing antigen immobilized on solid-phase materials were used for quick and efficient isolation of products that were relatively monospecific without the addition of other materials or dilution. These methods also had the enormous advantage that, by first eluting and discarding the loosely bound antibodies, the tightly bound, high-avidity antibodies could be collected, rendering the antiserum of higher affinity and thus reactivity. In addition, columns with immobilized antibody could be used to purify antigens. Despite the high cost of preparing a column containing several liters of immunoadsorbant, the columns could be used to strip contaminants from antigens or antibodies (sometimes valuable in themselves) and reused, sometimes over 100 times.

4.1.2 Antiserum Specificity/Relative Purity

As immunoassay methods have increased in sensitivity, the problems of contaminating antibodies have increased. An antiserum usable for in-gel analysis may fail completely when used for an enzyme-linked immunosorbent assay (ELISA) of the same analyte. The problem is simply the presence of low-affinity antibodies, which fail to produce precipitates in solution but are capable of forming complexes when bound to a solid-phase support. For this reason, affinity purification to remove such antibodies has become the norm. As a result, antisera produced today are usually far superior to those produced in the past; however, there is still the practical issue that antisera used for immunonephelometry need not be as monospecific as those for solid-phase fluorescent or enzyme-linked methods. The problem of an antiserum designed for a less-demanding procedure being applied to one requiring high purity, by an unsuspecting worker, is all too common an occurrence.

The subject of monoclonal antisera must be included and put into proper perspective.[10] When first introduced, monoclonal in-vitro-produced antibodies seemed to be a cure-all for immunoassay and the problems of contamination. Within a short time several shortcomings appeared. Producing a monoclonal antibody to a small, often poorly antigenic material was a great improvement over the traditional approach. Not surprisingly, firms that produced kits for serum protein assays felt compelled to explore the use of monoclonal reagents. The very basis of producing a monoclonal cell line dictates that each clone will produce antibody to one antigenic determinant. Unfortunately, this may happen to be of low avidity and nothing can be done to improve this except to search for another clone. This feature, so valuable in the measurement of moieties with few determinants or of restricted heterogeneity, worked against their use for measuring analytes with antigenic diversity – most serum proteins – because the monoclonal antibody only reacted with a small part of the spectrum of molecules present. As a result, the desire to measure large complex proteins failed with monoclonal reagents. More recently, cocktails of multiple monoclonal antibodies are solving these problems. There have been monoclonal antisera produced that clearly solve analytical problems for serum proteins. For example, antisera against cytokines, to the PI*ZZ form of α_1-antitrypsin and to some hormones have been successful. It remains, however, that for serum protein assays with proteins of excellent antigenicity and high concentrations, polyclonal antisera from the intact animal serve well and economically.

4.2 Immunoassays

4.2.1 Light-scattering Immunoassay

The bulk of serum protein assays done at present employ instruments that measure the amount of light scattered or absorbed by the immunoprecipitate developed with high-affinity and high-titer antisera. Two approaches have been used successfully.[11] The first is to direct a light beam of high-intensity light, broad-spectrum light or laser light at a cuvette containing a solution of the antigen-containing sample, to which is added a volume of specific antibody. A precipitate develops rapidly, often augmented by an enhancing polymer such as PEG-8000. At a specified time the amount of light scattered or absorbed by the immunoprecipitate in the sample is measured: the end-point. This is compared to a cuvette containing all reagents except for the sample. By subtracting the blank signal from the sample signal, the resultant can be converted to mass units from a standard curve of known concentrations of antigen.

The second approach is to monitor the rate at which the precipitate develops after the last fluid addition is

made to the cuvette. Rate analysis has several advantages over end-point analysis in that it is less sensitive to initial sample turbidity or pigments such as bilirubin or hemoglobins, it is not as sensitive to fluctuations in the formation of flocculent precipitates that develop after some minutes and it is unaffected by variation in the optical properties of the cuvettes.[12]

The reaction kinetics of all immunoassays can be described by the Heidelberger–Kendall curve (see Figure 2), which rises from near zero on the *x*-axis (the antigen concentration) and *y*-axis (the intensity of scattering) (*the ascending limb*) to a maximum (*the point of equivalence*) and then descends on the *y*-axis (*the descending limb*) at a high value of *x*. Often the signal disappears at very high concentrations. All forms of immunoassay can suffer from the same condition where either of the two reactants, antibody or antigen, is in great excess and the immune complexes become soluble. Of greatest concern in these systems is when the antigen concentration is in great excess. Because most assays of serum proteins have a dynamic range of approximately one order of magnitude, those serum proteins that can vary by more than one order of magnitude present a problem called antigen excess. It is the *bête noir* of immunoglobulin assays. Greatly increased levels, sometimes 20–50 times normal, can produce antigen excess signals low enough to be considered by the instrument as within the normal range. Various approaches, both within the assay system and by confirmation with other methods such as semi-quantitative serum electrophoresis, are used to overcome this problem. Antibody–antigen precipitates can be generated and measured in the fluid phase by immunonephelometry and immunoturbidimetry, in stabilizing gel techniques such as radial immunodiffusion and electroimmunodiffusion, or on solid particulate or planar surfaces by immunosorbent assays.

Figure 2 (a) The Heidelberger–Kendall curve, illustrating the relationship between antigen concentration and precipitate. The ascending limb is produced by small units of immunoprecipitate (insert, left arrow), the point of equivalence is the point at which the maximum amount of precipitate has developed (insert, top arrow) and the descending limb is created by increasingly soluble precipitates. (b) Rate nephelometric curves for two antisera produced against the same antigen, demonstrating the differing relationship between antigen concentration and rate signal for seemingly identical products.

4.2.1.1 Immunoturbidimetry Measuring the exiting light at zero degrees directly through the cuvette can perform the procedure described above. With increasing amounts of immune precipitate the light intensity decreases. However, there are a few caveats. At times, the immunoprecipitates are dense and may self-aggregate, thus allowing more than the expected amount of light to pass, or they may sediment out of the light path and give the same error. In most commercial applications, reagent concentrations have been tailored to minimize this problem. There is a conflict that at times can be difficult to resolve: by reducing the amount of reagent and sample to prevent flocculation and sedimentation, the sensitivity is reduced. Conversely, to improve sensitivity by adding larger volumes of sample, as in the case of a low-concentration analyte (e.g. C4, transthyretin), antibody of higher quality is needed. Clearly, antibodies of high affinity and titer are essential.

Intrinsic sample turbidity can be a handicap for low-level assays that require large sample volumes at low dilution. As sample turbidity increases, the baseline or blank value also increases toward a level where precision is compromised (at high optical densities). Clarification of samples by high-speed centrifugation, although a logical way to reduce intrinsic turbidity, can introduce the problem of removing some analytes with the chylomicrons. Serum proteins such as C4 and IgA, and sometimes IgM, will bind to the particles and be reduced to very low levels as a result of the procedure. Ideally, the patient preparation step of fasting must be underscored and a repeat sample taken. In some patients with certain forms of hyperlipemia, even this step will not clarify the

serum and results from measuring such samples should be regarded as suspect.

4.2.1.2 Immunonephelometry The difference between immunonephelometry and immunoturbidimetry is principally that the former measures the light scattered and the latter measures the light transmitted.[11,12] In other words, light that strikes particles and is deflected laterally. Different angles have been employed; a 90° angle has been used frequently with good results. Light reflected from particles strikes many surfaces before leaving the cuvette. Light that exits at 0° has been reflected internally many times. Particle size plays some role in the performance of each system. For small particles whose diameters are less than 1/20th the wavelength of the analyzing beam, the pattern of scatter is called Rayleigh scatter and presents a relatively symmetrical pattern about the axis of the beam. For larger particles, Rayleigh–Debye scatter presents a symmetrical pattern favoring forward angle scatter (toward low angles). Short-wavelength light is scattered much more than that of long wavelength but the requirement for a collimated light beam has made the use of the cheap helium–neon laser of long wavelength popular despite its poor sensitivity. Regardless of the angle at which light is measured, changes in the exiting beam intensity over time constitute rate nephelometry. The analysis time can be very rapid and in some assays time must be reduced to allow mixing transients to have passed before the reaction is measured.

4.2.1.3 Radial Immunodiffusion Not usually considered a light-scattering assay, the application of a set volume of serum to an antibody-containing gel slab is, in fact, just that[13] (see Figure 3). Observation of the immunoprecipitate is by indirect light: the Tyndall effect. The precipitates that have formed as antigen diffuses out concentrically from a central well produce an expanding ring (or rings) of immunoprecipitate that either stabilizes as all the antigen is bound and immobilized in the matrix or is measured at a set time after incubation at a set temperature. Growth and outward migration of the rings is the result of precipitation and resolution until all the antigen has been consumed. As diffusion continues, the precipitate dissolves on the inner aspect in the area of *antigen* excess and forms where *antibody* is in excess. Analyte concentration is derived from measuring the diameter of the ring in more than one axis (or the area) of precipitate as compared to rings of known concentration. Simplicity is the greatest asset of this method, which is still used in underdeveloped countries where budgets do not allow for the expensive instrument packages. It is also extremely efficient for workers developing new assays for research purposes using their own antisera.

There are a myriad of creative ways to employ gel diffusion to study antigen relationships: identity, non-identity or partial identity. There are several texts describing these simple yet elegant methods.[14]

4.2.2 Immunoaffinity Chromatography

Properly designed and prepared, the specificity of antisera allows the worker to perform quantification, purification, recovery and visualization. These techniques require scrupulous attention to the details of antibody specificity. The importance of this issue cannot be overemphasized. Confirmation of specificity remains the responsibility of the worker when applications other than those specified by the manufacturer are employed. Such problems were

Figure 3 Radial immunodiffusion in agar gel. (a) A demonstration of how many samples, including controls and clinical samples, can be applied to one plate. (b) The appearance of a matured test (bottom) with a sharp outer edge and a still expanding test (top) where the outer edge is diffuse. The images are shown as negatives.

one of the driving forces that propelled the United States Food and Drug Administration (FDA) to require clinical laboratories that used "in-house" tests or reagents to perform extensive validation studies akin to those performed by industry in what has been called the 510 k approval process.

4.2.2.1 Qualitative/Preparative The attachment of antibody or antigen to beads or other insoluble particles has been the mainstay of much of the work in antigen purification, either for detailed study or for the preparation of immunogens for immunization. In principle, the method relies on the attachment of antibody (or antigen) to a large surface area contained in a small volume, such as a porous bead. This large area is then exposed to a solution of protein. This procedure is usually performed in a column, although it can be performed in a flask. The gel is thoroughly washed with a benign solvent and then, when thoroughly flushed of contaminants, a solution of a chaotropic agent that dissociates the antibody–antigen complexes is passed through the column. The released material, now in solution – the effluent – contains the sought-after material. The solution is dialyzed to remove the chaotropic agent, leaving relatively purified material. The process can be repeated, using the recovered material to reduce the contaminants further. Of great importance is that the surface, once cleansed of the bound material, can be reused in the same manner. Industrial columns have been reused hundreds of times, thus greatly reducing the high cost of producing the column.

4.2.2.2 Quantitative/Analytical The same principle can be designed to view the stripped effluent, as it is eluted, as the sample to be analyzed. Proteins can be quantitated by spectrophotometry, which can be readily adapted to measure these effluent concentrations. Because the fluid initially applied to one column can be sent to a second column with different affinity, a serial analytical system can be envisaged. Such a system has been designed and used to assay 25 low-level analytes in series. This elegant work exemplifies all the affinity chromatography work that precedes it.[15]

4.2.3 Labeled Antibodies

The development of fluorescent, radioactive and enzyme markers attached to antibodies (and also to antigens) spawned an entire new industry. The requirement that antibody molecules (usually IgG) be coupled with these amplifying materials, exposed the proteins to rigorous conditions that often resulted in serious damage. Initially, shelf-life was short and performance characteristics were unpredictable within and between batches. Great advances in the quality of these products have been accomplished. The principal labels are listed in Table 5.

Table 5 Materials used to label antibodies

FITC	^{125}Iodine	Alkaline phosphatase
Rhodamine	Tritium	β-Galactosidase
Horseradish peroxidase	Latex particles	Rare-earth chelates
La Jolla Blue®	Gold	Acridinium ester
Isoluminol	Biotin	Luciferase

FITC, fluorescein isothiocyanate.

4.2.3.1 Fluorescence Immunoassay Each type of label presents advantages not offered by the others, but also disadvantages. The most disparate would be the exquisite sensitivity and ease of operation of the radioimmunoassay (RIA) countered with the general public's reluctance to deal with radioactivity, leading to expensive disposal problems. At the other extreme are fluorescence-labeled antibodies (FITC), which provide beautiful visual localization on tissue sections (Figure 4) with a stable and benign reagent that is easily visualized with ultraviolet microscopy, unfortunately countered with the rapid decay of the fluorochrome while being observed.[16,17]

Fluorescence has also been used as a means of quantitative measurement; however, the major problem of autofluorescence at the wavelengths used has required innovative instruments that measure fluorescence emission from fluorophores after a long time delay between stimulation and emission of light. Rare-earth chelates using europium have allowed workers to largely ignore background sample fluorescence at the stimulating wavelength and to delay analysis until the autofluorescent pulse has ended. Time-resolved fluorescence analysis has proven to be highly effective, even for low-level analysis. In a similar manner, sample autofluorescence has been reduced by selecting fluorochromes, which emit at wavelengths significantly removed from the stimulating wavelength. Autofluorescence therefore can be blocked by optical filters and is of little concern. In addition, selecting fluorophores that emit in the infrared region, where the sample contributes little background, resolves the same problem by a different approach.

The use of molecules that emit light directly or indirectly after enzyme activity on them has become a major field of assay development. Called chemiluminescence, the assay design fits that of ELISA assays and has extended the limits of sensitivity considerably. There are homogeneous and heterogeneous assays, as described below.[18] All such assays provide the feature of great amplification of what could be considered as the primary reaction. The steps that lead up to the generation of measurable light can be concatenated to allow precise assays

Figure 4 (a) Fluorescent microscopic images of immune complexes visualized in the glomerulus with FITC-labeled anti-IgG. (b) Antinuclear antibodies visualized with FITC-labeled anti-IgG on HEP-2 cell substrate.

into the low picogram range. These assays have become excellent methods for replacing RIA.

Immunoassays can be designed to be complex and multilayered with the goal of increasing sensitivity. These more complex assays fall into two categories: heterogeneous and homogeneous. The former has been supplanted in many cases by the latter for economic reasons; the former requires a separation step whereas the latter does not.

Heterogeneous. In brief, these assays present a specific antibody reagent to the antigen-containing sample where the reaction develops. After a specified time the sample is treated by the addition of precipitating agents such as polyethylene glycol, then by centrifugation or filtration. The precipitated antigen–antibody–fluorochrome complex is then measured optically. The separation step can be confounded by what can loosely be termed coprecipitation, meaning the development or pre-existence of precipitates. Agents that foster precipitation of the immune complexes can also promote precipitation of other proteins in the sample and coprecipitate the fluorophore. Nevertheless, these assays perform very well when properly designed.

Homogeneous. In this format, antigen-containing samples are mixed with unlabeled antibody, a conjugate of the target antigen with a nonfluorescent substrate, and an enzyme (e.g. galactosidase). Unlike the heterogeneous assay, this system will develop fluorescence only if the enzyme cleaves the bound substrate. Reaction of the bound substrate with the added antibody prevents this cleavage, thus inhibiting fluorescence. However, if there is free antigen in the sample it will bind with antibody, thus reducing the amount of antibody available. Some free unreacted nonfluorescent substrate will then be free in the solution and capable of being converted to a fluorescent material by galactosidase. At one extreme the sample devoid of the target antigen will exhibit maximum fluorescence, whereas samples with high levels will exhibit none. The reaction can be measured without the need for a separation step.

4.2.3.2 Enzyme-linked Immunosorbent Assay These extremely sensitive assays have evolved over the last three decades. Antibodies are tagged with an enzyme that, when bound to small amounts of antigen, can convert large amounts of substrate to colored products, thus enormously amplifying the signal.[19] ELISAs usually take advantage of the fact that surfaces such as glass and plastic passively bind materials such as proteins and carbohydrates. The initial step is the coating of the surface of the container (tube or well) with unlabeled antigen (A) or antibody (B) in the sandwich assays (see Figure 5). The diluted sample containing the antigen is applied and incubated under controlled conditions and then washed away. The remaining bound antigen is then exposed to a second antibody that is linked to an enzyme such as alkaline phosphatase, forming the "sandwich". This second antibody (B, C, D) can be identical in specificity to the antibody coating the surface, or be directed to a different aspect of the antigen, thus conferring increased specificity. It may also be an antibody to the species that has provided the first antibody (D). The washed wells are then developed with proper substrates to produce color, which is then read spectrophotometrically. Many automated devices are now available to perform most of the operation with little operator intervention.

Figure 5 Diagrammatic representation of the direct form of ELISA. (Adapted from Crowther.[19])

As with other immunological methods, creativity has produced a great diversity of protocols with unique features to address special problems. The nature of the multilayered assay allows antigen to be substituted for antibody on the surface of the well, thus providing a means of assaying antibody levels. In such a circumstance, the first antibody is specific for the coating antigen – the antibody being measured (e.g. antibody to the Lyme disease agent, *Borrelia burgdorferi*) – and the second antibody is labeled, which, after separation and washing, provides the signal. It is a simple concept to envisage that, because each step provides amplification, added steps will increase sensitivity. Additional steps can be introduced to inhibit each phase of the assay, thus providing a competitive format. Coupled with a variety of tags and antibodies, virtually any antigen–antibody system can be designed.

4.2.3.3 Radioimmunoassay In exactly the same format as described above, RIAs of extreme sensitivity and specificity can be developed.[20–22] Despite the public aversion to radioactivity, these assays persist and are used safely worldwide. The minuscule amounts of radioisotope employed require Herculean measures for storage and disposal of spent reagents that are far beyond the risks involved. Most RIAs are performed in tubes, in automated devices, with the final step being to measure photon emission in a scintillation fluid (an organic solvent) as the result of radioactive decay of the isotope.

4.3 Biospecific Affinity Chromatography

Although not an immunological method, utilizing the affinity of a protein for a specific material is so similar in all aspects to the method described in section 4.2.2 that it is described in this section.[23] It is an effective means of purifying or quantifying certain proteins. Historically, it was introduced in the early part of the 20th century. It is still used extensively in industrial applications for clarifying, decolorizing and extracting desired or undesired materials. The first affinity adsorbent was charcoal and it is still used in the food industry. There are a myriad of materials that can be used in this way. For serum proteins the activity against target substances such as enzymes, immobilized ions, DNA, dyes, heparin, and the endless list of antigens or antibodies are examples. Very recent use of nanoparticles of lipid for the trapping and removal of specific moieties has particular promise in both purification and diagnostic applications.

Charcoal, microporous glass, ceramics and similar materials possess immobilized ions for trapping or removing proteins, particularly those with hydrophilic groups. Plastics or other hydrocarbon polymers can provide potent binding sites for hydrophobic proteins such as the lipoproteins.

Binding to insoluble matrices also provides a means of further characterizing proteins. The association of a protein with a specific target can vary within a protein species, thus providing a means of further classifying a ligand. Once a material is bound, elution or dissociation can be induced by stepwise changes in eluant pH, ionic strength, ionic content, temperature or specific dissociating agents such as dithiothreitol, glycine, guanidine, detergents and other chaotropic agents.

The ligand can be a plant lectin with specificity for a protein, or even subspecies of animal proteins.[24] These materials are widely employed to prepare and isolate large amounts of material for study. The number of commercially available lectins is steadily increasing as their importance is appreciated: more than 100 have been identified. Many of these materials are extracted from seeds (ex.: concanavalin A) and others from bacteria (staphylococcal protein A). Presumably their original biological purpose is being exploited in these laboratory procedures.

4.4 Chemical Assay

Some of the analytical methods that can be applied to proteins are used infrequently or are so specialized as to be employed only in the research setting. These will not be dealt with other than to mention them and the information that they provide.[5]

4.4.1 Colorimetric

The measurement of protein concentration spectrophotometrically can use many different features of the protein family: the nitrogen content, presence of peptide bonds, the ability to bind dyes, and the ability to form light-scattering precipitates with specific reagents. These methods are all destructive forms of analysis. They are widely employed but, like all forms of analysis, they have

both advantages and disadvantages. In general, these methods cannot be used if unwanted turbidity develops during the analysis. Because many are still in use to determine the protein content of difficult materials, they will be mentioned here.

4.4.1.1 Nitrogen Content Nitrogenous compounds in the serum are principally protein;[5] however, in urine, where protein content is also of great clinical and research importance, the high nitrogen content of urea makes this method unusable unless proteins are separated by dialysis. Nitrogen content assay is now used rarely, except in the investigative setting where fractions or purified materials are examined. This method also has the advantage of being able to measure the nitrogen content in whole tissue or in precipitates that are sufficiently turbid to preclude other common forms of analysis. Several techniques have been devised in the past and still have an important role to play, although in general they require large amounts of sample.

The *Kjeldhal method* relies upon the digestion of nitrogen-containing material by sulfuric acid. The digestion produces ammoniacal compounds that develop a specific yellow color with the highly basic, mercury-containing Nessler's reagent. This method, although excellent, is subject to many interferences and requires careful technical attention to prevent spurious charring and turbidity.

4.4.1.2 Peptide Content The *Biuret reaction* is directed to the presence of at least three adjacent peptide bonds.[5] It therefore has the advantage of not being reactive with other nonpeptide nitrogenous compounds. Free amino acids do not affect the reaction but small peptides can interfere, hence the method again is not usable in measuring urine protein directly. The addition of an alkaline copper sulfate-containing reagent produces color detectable at 557 nm. Because individual species of proteins contain different numbers of peptide linkages, some workers have listed Biuret numbers to correct the reading. It is clear that this method when used with a gravimetrically standardized amount of total serum protein, bovine serum albumin or even human serum albumin gives different results.[25] As a result, clinical samples containing disturbed concentrations of serum proteins can give very aberrant values.

The *Lowry method* is a more sensitive assay. The amino acids tyrosine and tryptophan, characteristic of proteins, are the focus of this method. The phenol Folin–Ciocalteau reagent containing copper ions produces a color detectable at either 720 or 660 nm, but like the other methods the Lowry technique is not suitable for materials that produce turbidity.

A further increase in sensitivity is achieved by the *ninhydrin method*. Like the Biuret reaction, different protein species produce different relative values.

4.4.2 Dye Binding

One of the most commonly used methods for measuring albumin in serum relies on dye binding.[5] Among these are bromocresol green and bromocresol purple, the dyes used in most automated chemistry analyzers. It must be remembered that those proteins that bind dyes also bind other materials as their physiological abilities dictate. Moieties such as bile pigments, anti-inflammatory medication such as acetylsalicylic acid, penicillin and many medications bind to albumin and in the instances where these materials are in high concentration the binding of reagent dyes can be interfered with to a significant degree. The most difficult situation is in severe liver disease, where high levels of bilirubin coupled with low levels of circulating albumin can produce falsely low values. In such situations, the immunochemical determination is believed to be superior.

4.4.3 Precipitation Methods (Nonimmunological)

4.4.3.1 Destructive Primarily applied to CSF total protein analysis, the use of certain acids to precipitate protein is widespread. Trichloroacetic acid and sulfosalicylic acid are the main agents used. A problem with these commonly used techniques is that glycoproteins are very resistant to precipitation and remain in solution.

These techniques are used for measuring urinary total proteins but they are not to be relied upon because other materials also precipitate, such as the Tamm–Horsfall protein and proteins from the epithelium of the genitourinary tract.

4.4.3.2 Nondestructive All proteins are subject to precipitation in the face of an increasing concentration of certain neutral salts, such as ammonium sulfate, sodium sulfate, Rivanol (a long-chain alcohol) and polyethylene glycol.[25] In general, proteins come out of solution in relation to their isoelectric point: fibrinogen first, at lowest salt concentration; and then the immunoglobulins. Ultimately, some proteins will remain in solution in saturated solutions of the salts. Rough quantitative methods have been devised using these properties. Rivanol is the exception, precipitating protein in approximately the reverse manner.

4.5 Physical Properties

Analysis of serum proteins can be accomplished efficiently by measuring individual physical properties of a species in question.[5] With the help of modern instruments many

aspects can be used to describe the characteristics of a sample, both in quantity and quality.

4.5.1 Optical

4.5.1.1 Refractometry As light passes from one medium (air) to another (aqueous solution), the angles to the perpendicular at the boundary can be measured as the refractive index. The total solute content of the liquid affects the index of refraction in a proportional manner so that after dialysis against a ''blank'' solution it can be used to measure protein content. The method has the advantage of being nondestructive. It has been used extensively to measure total protein in the past but it is no longer used where sophisticated instruments are available. It remains of use, however, largely in the research setting when an approximation of the protein content of a small volume of a purified product is needed: the tested volume can be recovered.

The same principles are employed in analytical ultracentrifugation (see section 4.5.11).

4.5.1.2 Spectrophotometry A mainstay of protein quantitation in the research setting has been spectrophotometric measurement of light absorption at a wavelength of 280 nm.[25] This wavelength is usually selected because it represents an absorption peak for proteins rich in tyrosine, tryptophan and phenylalanine. Not surprisingly, when purified proteins are examined for the absorption spectra, each is slightly different from the others as a result of differences in their amino acid composition. Nevertheless, measurement of absorbance at 280 nm is a very useful, nondestructive method of approximating the total protein content at concentrations of $0.05–2\,mg\,mL^{-1}$. This form of analysis is widely employed in monitoring immunoaffinity column effluents. Ultraviolet absorption using shorter wavelengths develops problems because of interference from other substances, including amino acids. At higher wavelengths, protein absorbs very little.

4.5.2 Mass/Gravimetry

Although seemingly crude, there is logic for using this technique as a benchmark for standards. There are several criteria that must be met before the method is usable. The protein to be measured gravimetrically must be obtainable in sufficient quantity to yield an accurate reading in modern balances. New instruments are exceedingly accurate, precise and sensitive when kept on proper maintenance programs. High-sensitivity instruments can easily reach a precision of less than 1 mg. Nevertheless, careful calibration must be performed on a regular basis. In the case of proteins, their propensity to become hydrated from ambient air requires that the purified material be sealed in dry nitrogen after removal of as much water and salts as possible. The method requires no indirect comparisons and when sufficient material is available it is a benchmark means of analysis. Associated nonprotein constituents such as sugars and lipids also contribute to the weight.

4.5.3 Viscosimetry

A measure of molecular size and configuration of solutes versus the solvent alone constitutes a measurement used clinically as an alternative to the trusted erythrocyte sedimentation rate. Measurement of the viscosity of whole human serum or plasma is a very approximate and imprecise measure of the average viscosity of all proteins in the sample and is the result of the concentration and shape of the major fractions.[5,25] Albumin is in the highest concentration range but, being a globular protein, its viscosity-inducing effect is minimal. IgG is more elongate and of intermediate concentration, therefore contributes significantly. The very large proteins IgM and α_2-macroglobulin are both of much lower concentration yet do contribute significantly. All other proteins combined contribute very little effect. In plasma, however, fibrinogen – an elongate, fibrillar protein – contributes to the total viscosity in a major fashion. Although in some countries plasma viscosity has replaced the erythrocyte sedimentation rate, it is clinically less useful. However, it is amenable to the distribution of standardized materials for quality assurance programs.

The greatest clinical use for serum viscosity is for the cluster of diseases known as the monoclonal gammopathies. Some patients have markedly elevated levels of IgM or polymeric forms of IgA or IgG. These intermediate or large-sized immunoglobulins, sometimes elevated from 10- to 100-fold over normal, have a tendency to increase the viscosity of plasma to a hazardous degree. In these instances it is critical that the physician be aware of the presence of the hyperviscosity syndrome, which includes reduced or stagnant blood flow to critical tissues such as the brain, myocardium, pulmonary circulation and the kidney. Symptoms that develop reflect stagnation in these tissues, e.g. seizures, blindness and myocardial, renal and pulmonary failure.

4.5.4 Sieving Chromatography

Column chromatography employing beads of different pore size has been used extensively to purify proteins for special studies and for immunization. A wide range of particulate materials are available commercially for separating protein populations by their molecular size. Even small exclusion volumes allow solvents and salts to enter their pore volume and to be retarded as they

pass through a column. Larger molecules are retarded by entry into gels of appropriate porosity. The simplest use has been to exchange buffers in lieu of dialysis. The protein enters the top of the column in one buffer system, perhaps a denaturing one, and exits in a neutral saline solvent a short time later. Large pore sizes will retard small proteins, allowing larger proteins to exit the column first. Increasing the pore size allows only macromolecules to exit with the exclusion volume. Gels with very large pore size tend to be deformable, resulting in poor flow rates unless the column is pumped in reverse to prevent packing. Often a dye marker such as blue dextran is used to monitor the architecture and performance of a column. The method remains a mainstay of industrial protein purification.

4.5.5 Rotatory Dispersion

All constituent amino acids except glycine are asymmetric. As a result, polarized light is shifted on passage through a solution of polypeptides or serum proteins in a left-handed manner, i.e. levorotatory.[25] This left shift is very sensitive to any denaturation but under carefully controlled conditions and with good instruments it can provide important information about the steric arrangement of amino acids along the polypeptide chain.

4.5.6 X-ray Analysis

Structural features of proteins that can be obtained in pure form and crystallized can be examined at the atomic level with monochromatic X-ray beams.[25] The complex pattern thus produced can be converted to three-dimensional images with modern software programs and modest hardware. The method remains a research tool.

4.5.7 Electron Microscopy

For serum proteins the contributions of electron microscopy[26] have been limited by the resolution of the instruments, which is at best a few angstroms for some instruments, whereas protein size exceeds this. With the addition of heavy-metal shadowing with gold, osmium, and others, features not seen with standard viewing become evident. Nevertheless, combining images of relatively large proteins with X-ray crystallography has allowed researchers to reconstruct what is believed to be the actual physical shape of some proteins, thus enhancing our understanding of function. Blood proteins such as fibrinogen, C-reactive protein, retinol-binding protein, many serum enzymes and immunoglobulins have been imaged, yielding valuable information to aid in understanding their function.

4.5.8 Stoichiometry

All serum proteins whose biological function includes combination with other moieties can be described in terms of molar ratios because they exist in normal and abnormal states. The structure of each molecule includes the description of the number of subunits in the whole and whether they are repeats or are novel. Most serum proteins are composed of an assemblage of subunits linked by bridges or bonds that are subject to dissociation by various enzymes, chaotropic agents or other agents. Such subunits may retain function, as in the case of immunoglobulins, where dissociation can proceed to the point where only the binding site at the end of the Fab′ fragment remains. This ability to bind other moieties by subunits provides useful practical information for clinical medicine: e.g. the binding of one molecule of hemoglobin to a single molecule of haptoglobin, regardless of the haptoglobin subtype; the 1 : 1 ratio indicates that the same mass of hemoglobin will be bound by a given mass of haptoglobin type 1-1 as by many times the mass of the macromolecular isoform type 2-2. The serum level, without the knowledge of the phenotype, can be very misleading as to hemoglobin binding capacity.

A frequently measured ratio is the percent of transferrin saturation with iron or the total iron binding capacity. Normally transferrin, the iron binding protein, remains less than totally saturated with two molecules of Fe^{3+}. In the common hereditary iron storage disease hemochromatosis, high levels of saturation occur, providing a laboratory finding that is often the first sign of the disease. Calculating the transferrin saturation is the most precise means of determining the degree of iron saturation; values above 70% for males and 62% for females are grounds for concern.

In a similar manner, the amount of lipid bound to lipoprotein B, which affects the density, yields information of value in determining risk from atherosclerotic coronary artery disease. The more dense of the low-density lipoproteins (LDLs) appear to have greater atherogenic capacity than the less-dense forms, irrespective of the amount of protein present.

4.5.9 Chain Structure

All proteins possess a linear chain of amino acids as their original backbone. During post-translational modifications, portions of the chain are deleted, cuts occur and new three-dimensional structures are created. Most proteins also possess a secondary branching structure, also composed of amino acids. Most species possess a tertiary structure as the result of portions of these complex chains folding or looping back on themselves and attaching by hydrogen bonds. It is these tertiary structures that

dictate the function for each unique species. Attached to the amino acid backbones or side chains are additional chains composed of carbohydrate, nucleic acids or units of mainly lipid. These also dictate function, either toward other entities or by the manner in which they transport or store the moiety.

The protease inhibitor α_1-antitrypsin has a single chain of 394 amino acids from which carbohydrate side chains are extended (see Figure 6).[3] These side chains can assume either a biantennary configuration or a triantennary form, which combine to create different isoforms whose physicochemical characteristics also differ. The differing isoforms seen in isoelectric focusing result from the carbohydrate side chains terminating with sialic acid residues. As a result, their isoelectric points vary considerably from each other, but under proper conditions of acid pH and gel pore size they separate well in polyacrylamide medium.

The importance of these forms is that certain phenotypic forms of α_1-antitrypsin are synthesized at low levels, placing the host at risk from unrestrained leukocyte proteolytic enzyme activity in the lung spaces, which will progress inexorably to pulmonary failure. The principal reason for searching for these isoforms is to institute lifestyle changes that can mitigate proteolytic digestion and the development of emphysema. Three alleles of the 70 or more described have clinical significance: PI*Z, which produces no more than 10% of the normal amount of inhibitor; PI*S, which produces about 30%; and the exceedingly rare PI*null, which produces none. These figures compare with the normal synthetic product of 50%. In combinations, the Z, S and null alleles can produce subnormal levels of α_1-antitrypsin: PI*ZZ (10–20%); PI*SZ (30–50%); and PI*SS (~60%). Of practical importance is that when most other alleles are present with a deficient allele, levels of the inhibitor are sufficient to prevent proteolysis but the implications are important to the next generation or sibling. A couple who are both heterozygous have a 1 in 4 chance of having an affected child. In Western Europe and North America, the population incidence is 1:1700–1:3000 for the ZZ phenotype.

Haptoglobin, the serum protein that binds hemoglobins in the vascular spaces, exists in three isoforms (see Figure 6).[3] The α-chain is polymorphic (α_1F and α_1S; a third form α_2 is the product of a partial gene duplication with an α-chain twice as long as the α_1 form) whereas the β-chain is not. The products of these combinations are named haptoglobin type 1-1 (one α- and two β-chains), haptoglobin type 2-1 (one α_1-, one α_2- and two β-chains) and haptoglobin type 2-2 (two α_2-chains and two β-chains). These combinations result in molecules of sizes 85, 120 and 160 kDa. The type 2-1 and 2-2 polymers are of very large size, which in high-resolution electrophoretic

Figure 6 (a) Representation of α_1-antitrypsin isoforms and their branching carbohydrate side chains. (b) Representation of the three isoforms of haptoglobin and their composition of the three chain types α_1, α_2 and β. (Adapted from L.O. Hansson, Karolinska Hospital, Stockholm, Sweden.)

systems produce distinct ladders of haptoglobins, whereas type haptoglobin 1-1 remains a monomer and thus migrates as a single band.

The function of these molecules is stoichiometric binding with free hemoglobin that, as a result of normal red cell turnover, is released into the circulation at low levels. Therefore, any process that increases the release of hemoglobin will consume haptoglobin and depress serum

haptoglobin values if consumption exceeds synthesis. Because of the differing mass of each haptoglobin isoform (e.g. in Caucasian populations, a ratio of 1 : 1.5 : 2), serum levels can only relate to hemoglobin binding capacity as functions of that ratio. Persons with the smallest molecular form will be affected by low-level hemolysis to a greater degree than those with the high-molecular-weight form. Under normal conditions the total haptoglobin pool can bind no more than 3 g of hemoglobin before it becomes depleted. Because of its small molecular weight (14 kDa), hemoglobin will be lost via the kidneys unless it is bound to haptoglobin. There are a variety of ''impact'' sports that result in red cell damage. Red cells are crushed and burst as the result of sudden forceful contact. Originally termed ''bongo hemolysis'' or ''drummer's hemolysis'', it is now recognized that many sports such as hand ball and jogging cause red cell damage. In addition, prosthetic heart valves and roughened surfaces in diseased vessels produce hemolysis. In the first instance cells are physically damaged by valve closure, and in the others because of violent turbulence around the diseased vessel surface: the Venturi effect. All patients placed on cardiopulmonary bypass have accelerated red blood cell damage as a result of cell contact with plastic surfaces and foaming.

4.5.10 Component Parts

Of great importance is the ability of some transport proteins to combine with hydrophobic substances such as lipids, e.g. cholesterol and triglyceride, transporting these hydrophobic substances in plasma to cells as an energy source. Lipids absorbed from the gut are quickly surrounded by the hydrophilic molecules of phospholipids, rendering them soluble in plasma or lymph. This surface coating then accretes the apolipoproteins to form particles whose fate and function are largely dictated by the type of protein associated. Of the major classes, high-density lipoprotein (HDL) follows a different path in that rather than incorporation of lipid particles, HDL incorporates lipid in molecular form. There are at least ten forms of lipoproteins that, in various combinations, create six major classes. Chylomicrons and chylomicron remnants are of intestinal origin, three – VLDL, intermediate-density lipoprotein (IDL) and LDL – are of hepatic origin and one other, HDL, is from hepatic and non-hepatic origin. Yet another classification scheme has been adopted: LpB, LpB : LpE, LpB : CIII, LpB : (a), LpAI, LpAI : AII, LpAI : CIII. Regardless of the classification scheme, each member has a unique role in the metabolism of lipid and the ultimate result of their metabolism, whether normal or predisposing to disease.

4.5.11 Sedimentation Analysis

Between 1923 and 1926, Svedberg developed the technique of ultracentrifugation.[25,27] The technique was so fundamental to the development of protein biochemistry that he was awarded the Nobel Prize in 1926.[4] Under the large gravitational forces of high-speed centrifugation, proteins in solution will sediment differentially at a rate that depends on their mass and, to a minor extent, their shape. By using a solvent with a density gradient, proteins may be separated into layers that reach a stable equilibrium with the density gradient. Under these circumstances, shape no longer influences sedimentation and their molecular mass may be determined. The layers are only stable during centrifugation and so the proteins must be visualized by optical means while the centrifuge is still running and after an appropriate time.

The centrifugal forces employed must be intense and can be achieved only in specially designed instruments. If density gradients are not used, the physical shape of the protein may affect the sedimentation characteristics, especially if the molecule is of a fibrous nature, such as fibrinogen, or globular, such as albumin. When complex solutions are being studied, the proteins may bind to one another, thus altering the rate of sedimentation. This can be used to advantage as evidence of molecular interaction.

Sucrose may be used to create stable gradients through which the test analyte sediments until its buoyant density is reached. Obviously, reaching sedimentation equilibrium can result in flotation when the protein being studied rises rather than sediments. Lipoprotein research has been much advanced by this approach and very large amounts of relatively pure lipoproteins have been recovered for further analysis.

Analysis is performed by continuous observation though the side of the cell using ultraviolet light reflected to an optical visualization system or onto photographic film. The Rayleigh interferometric system is the basis of most systems, where a beam of light is passed through the sides of a cuvette while the ultracentrifugal run is in process. The beams, having been split by the optical system, one passing through the sample and the other directly to the detector, produce interference patterns where boundaries of protein layers occur. More recently, laser illumination has been used to advantage. Measurement of the velocity of the moving boundary between pure solvent and the sedimenting layer of analyte yields the sedimentation coefficient, which is given in Svedberg units (S^0) to honor its discoverer. Molecular masses are recovered from these measurements.

For a period in the late 1960s and early 1970s ultracentrifugal analysis was used to advantage in sophisticated centers caring for patients with diseases of the immune system such as myeloma and Waldenström's disease. With

the advent of inexpensive and precise immunochemical means to quantify these proteins, whose molecular weights have clinical implications for blood flow, sedimentation analysis has become merely a research tool.

Flotation analysis is the application of the same principles to the lipid-rich family of lipoproteins. Ultracentrifugation with the proteins suspended in solutions of varying density results in each protein–lipid micelle floating, to yield flotation constants that provide information about the lipid and protein content.

4.5.12 Physical Features

When whole serum or its fractions can be classified by the effect of external forces on the sample, a new series of descriptors develop, many of which have clinical implications.

4.5.12.1 Thermostability Exposure to cold induces normal physiological events that are all too familiar and often troublesome; however, for individuals who have abnormal serum proteins, especially certain monoclonal immunoglobulins, exposure to cold can be life-threatening. IgM monoclonal components and rarely those comprised of IgG quickly precipitate or gel in the cold, with the result that circulation in chilled areas such as the ears, nose, fingers and especially the toes can halt completely, with resultant gangrene if allowed to persist. In whole blood or plasma, cryofibrinogen can cause gelation, as can very high levels of immunoglobulins with cold-agglutinin activity. There have been rare instances of similar proteins with sensitivity to elevated temperatures (37–45 °C). The consequences are the same as for cryoproteins. In the laboratory, technologists must be constantly alert to thermolability, which is detectable upon thawing of frozen samples or simply in serum samples exposed to refrigerator temperatures overnight or for several days. Gels or precipitates in samples being analyzed can cause serious instrument problems (see Figure 7).

Free monoclonal light chains or Bence Jones protein, usually found in urine, was originally described as a protein that precipitated while urine was heated but dissolved completely on boiling. As the sample is cooled, precipitation again appears but disappears at lower temperatures. This classical behavior is often lacking in this group of interesting patients, however.

4.5.12.2 Binding to Surfaces Some serum proteins, such as fibronectin, have a remarkable affinity for plastics and glass such that preparing a sample for analysis requires effort to prevent this.

4.5.12.3 Color Certain serum proteins can impart unusual color to a serum sample. Normally serum has a yellow tinge as the result of binding of pigments to albumin, but at times the yellow color can be intense or even brownish when the patient is intensely jaundiced, is receiving high levels of penicillin or has been exposed to very large doses of vitamin A as the result of dietary fads (carrot juice). Occasionally, serum takes on a greenish-blue color in pregnancy due to estrogen stimulation of ceruloplasmin synthesis, which contains copper. The serum is green as a product of yellow albumin and blue ceruloplasmin. The most common discoloration of serum is because of the presence of hemoglobin or myoglobin, imparting a pinkish to reddish to brownish color that can interfere with some spectrophotometric analyses if intense. However, artifactual release of hemoglobin and binding to haptoglobin in vitro does not significantly alter the measurement of that protein. In rare instances of crush injuries or severe intravascular hemolysis, free hemoglobin can be visible and will make analysis of haptoglobin impossible: values will be zero.

Figure 7 Cryoprecipitate of monoclonal IgM developed after overnight refrigeration in an initially clear serum. Note the large amount of dense material at the base of the tube.

4.5.13 Amino Acid Analysis

A technique now reduced to practical routine in research laboratories is amino acid sequencing. A purified material is digested sequentially and the product of each step is analyzed to determine its nature and contribution to the whole.

4.5.14 Fluorescence Polarimetry

Illuminating molecules at specific wavelengths may result in re-emission of light at different wavelengths or at different axes. The re-emitted light can be quantitated accurately for certain proteins in their native form (see

Table 6 Scale of detection limits

Scale of concentration (log scale)						
Least sensitive						Most sensitive
Albumin ($g\,L^{-1}$) 10^{-1}	C3 ($mg\,L^{-1}$) 10^{-3}	AFP ($\mu g\,mL^{-1}$) 10^{-6}	IgE ($ng\,mL^{-1}$) 10^{-9}	Interleukin-6 ($pg\,mL^{-1}$) 10^{-12}	Research ($fg\,mL^{-1}$) 10^{-15}	Research ($ag\,mL^{-1}$) 10^{-18}

Table 6) or after coupling with compounds that render them fluorescent.

4.6 Electrophoresis

With the introduction of protein separation in an electric field by Tiselius, Svedberg's student, in 1926, investigation of blood proteins took an enormous leap forward.[28,29] At first, methods were labor intensive and took many hours to complete, but since the 1950s they have gradually become rapid, they require microliter quantities of sample and in some cases they are fully automated. Nevertheless, more simple forms of electrophoretic separation remain in widespread use and still retain an economic edge over the automated systems. The interested reader will find that texts on this subject were mostly written during the development phase of the methods and that since these methods, in all their permutations, have become routine little new has been written. Books on the topic are included in the references rather than attempting to select from the enormous number of important papers.

Separation in an aqueous medium results in a variable degree of interaction between the protein and the support matrix used for separating the sample (Table 7).

A great number of supports have been tried over the past 45 years; all share the same basic goal – to prevent ohmic heating from producing convection during migration. Although some convection is inevitable, good separation requires that it be kept to a minimum. In the same way, the effects of diffusion and evaporation, again inevitable, must be minimized. Both goals are met by the introduction of a matrix composed of an insoluble material. Ideally the matrix should not have a charge of its own. In practice, however, many matrices do have electrical charge at the pH of conventional buffers and set up what is called electroendosmotic flow. The effect is that, in its tendency to migrate in the solvent yet being fixed in position, the matrix effectively "pumps" solvent in the opposite direction. Although not totally desirable, it does work to advantage in that proteins with cathodal mobility – a positive charge at the pH of the buffer – are moved backwards and separate in the same manner as those that migrate forward to the anode. With the introduction of hot-water-soluble gels there was the possibility to adjust this endosmosis to suit certain applications. Agarose, a component of agar used in the early phases of this work, provided a variety of features selected by the manufacturer that allow control of endosmosis, in some cases eliminating it completely. Another widely used matrix is a polymerized gel that can be tailored to fit a wide variety of needs. The monomer acrylamide is induced to polymerize by cofactors such as oxidizing agents or ultraviolet light to produce a strong clear gel that can be cast in any form.

Table 7 Separation features for electrophoresis

Solvent	Usually aqueous
Solute	Usually a salt with buffering qualities
pH	Selected to straddle the isoelectric point of the proteins to be studied (~8.6)
Matrix	Selected to prevent convection
Temperature	Usually cool to aid in dissipation of heat generated by the current flow
Voltage	Varying from several hundred to thousands of volts
Current	Direct current and kept to a minimum to prevent ohmic heating
Additives	Selected to modify the species being studied to provide proper separation of bands and to: – dissociate certain species – remove certain or all lipids – prevent coagulation – retain separated species in as near native form as possible for further study

Of great importance was the realization that both specialty agaroses and polyacrylamide could be tailored to produce controlled pore sizes. This provided the ability to produce pore-size gradients so that in an electric field proteins would migrate to a pore size level beyond which their molecular dimensions would prevent further movement. Polyacrylamide, and to a lesser degree agarose, allows pH and size gradients of infinite configurations and in combination. This technique is now a mainstay of protein investigation. After separation, proteins may be visualized by fixation and staining, immunoprecipitation and staining or by direct ultraviolet observation.

4.6.1 Continuous Zone Electrophoresis

As the name implies, the pH and other physical features of the separation matrix and buffer reservoirs are uniform throughout the separation. In an electrical field, ions and

Figure 8 Serum protein electrophoresis in agarose gel at pH 8.6. The anode is at the top and the cathode at the bottom. Proteins separate according to their isoelectric points at the buffer pH. Individual bands (α_1, α_2, C3, Ig, etc.) are actually composites of many superimposed proteins. The apparent exceptions are the heavy bands seen in lanes 1 and 2, which are due to monoclonal immunoglobulins.

Figure 9 Isoelectric focusing at pH 4.2–4.9 in polyacrylamide gel, showing the distinctive bands of the common phenotypes of α_1-antitrypsin. The anode is at the top.

Figure 10 (a) Immunofixation of a cryoprecipitated monoclonal IgG. The sample has been precipitated and washed with saline. The electrophoresis of the original serum and the washed precipitate have been developed with individual antibodies to different proteins, demonstrating that the band seen in the serum electrophoresis on the left is of the IgG class and lambda light chain type. (b) Immunoelectrophoresis developed with three antisera. The samples were placed into the wells and electrophoresed. The troughs in the gel were filled with antiserum and then allowed to diffuse and form specific immunoprecipitate arcs. Fine detail can be observed on magnification.

water move in the direction dictated by their individual p*I* values. Part of this process includes the migration of buffer as a result of electroendosmosis, mentioned above. Many materials have been employed as the separation matrix, whose main purpose is to prevent convection and provide stability within the fluid phase. Early in development came paper, starch, agar gel and even gelatin; later came cellulose acetate, agarose (see Figure 8) and then acrylamide[30] (see Figure 9). Still later, agarose derivatives were introduced as well as combinations of agarose and cellulose acetate. Permutations included antibody cast within the separation gels (see Figure 12) or in wells opposed to the sample well for precipitates to develop in the intervening area (see Figure 10b). The creativity of the worker allowed many novel designs.[14]

A product of advanced technology has been the commercially available, automated capillary zone electrophoresis. Proteins separated on a matrix coated onto the inner surface of a capillary are eluted from the capillary tube to be detected by ultraviolet absorption. Resolution is remarkable, migration time is only a few minutes and sample sizes are minuscule. The format includes automated read-out and graphic result presentation. Coupled with this approach is an application of specific antibody to certain samples, incubation and electrophoresis of the remaining solution. Called ''subtraction capillary zone electrophoresis'', it has application where a monoclonal protein is present and its class identification is desired. By the addition of specific antibody, the protein in question is removed, thus disappearing from the resulting pattern.

4.6.2 Isoelectric Focusing

The next major step came with discontinuous buffers. In this process, strips of matrix are formed in thin glass cylinders or slabs of gel, and recently in very thin hollow silica fibers containing buffer.[28,31] In such a system the acrylamide gel matrix is divided into two phases: the buffer phase at the top and the stacking gel and separation gel at the bottom. The protein sample is placed above a large pore or stacking gel, where the species are able to arrange themselves according to their isoelectric point (p*I*) without being separated by size or configuration. Below this is a third phase, where the pore size is tailored to separate the species according to their velocities (see Figure 9).

The basic structure of each protein species and subspecies dictates differences in p*I*. To capitalize on these differences, which may be very minor, separation occurs over a stable pH gradient created by the incorporation into the matrix of ampholytes (non-protein, low-molecular-weight compounds of set p*I*), which produce pH gradients into which the proteins migrate. Moving toward their isoelectric point, at which their net charge is zero, creates an ever-decreasing zone width for that protein. The result can be a remarkable display of protein bands. This extreme resolution presents a limitation in that at the isoelectric point, where the p*I* is zero, high concentrations of protein tend to form a precipitate unless the procedure is done in very dilute solutions. Many types of ampholines can be acquired commercially to cover the pH zone desired. Gradient pumps are available to assist the worker in producing tailored pH gradients as needed.

4.6.3 Isotachophoresis

In this form of electrophoresis proteins separate into adjacent zones that all migrate at the same rate.[31] Ultimately the bands separate into separate components, with no overlap, and as they are continuously moving down a tube or capillary they can be collected and analyzed. The procedure lends itself to the preparation of pure protein fractions. The separation is by charge alone and can be done in a free liquid but is usually done in a gel slab. A gel of optimal pore size for the molecules of interest is selected, with separation being the result of the pH gradient. As a result, the technique is extremely effective in the study of charge isoforms of a single species. Contaminating proteins are either swept beyond the moving front or are prevented from entering the gel area where the desired proteins separate.

Isotachophoresis can resolve a high concentration of protein into individual bands without promoting precipitation as seen in isoelectric focusing. As a result, the method is able to resolve milligram quantities for preparative purposes.

4.6.4 Immunofixation

This two-step process combines electrophoresis on a support matrix in whatever form, as described above, with a second passive step where antibody is applied to the surface of the gel.[32] This simple step rapidly "fixes" the protein of interest into the matrix. Subsequent washing removes all unreacted antibody and serum proteins so that when the matrix is stained in the usual manner only the antibody–protein complex remains visible. The advantage is that the results are unambiguous and can be compared, side by side, to the original electrophoretic separation. This is often an adjacent comparison strip to minimize slight changes in migration conditions developing during the run (see Figure 10a). Virtually any serum or other body fluid protein can be processed by this technique as long as the antiserum is specific and of sufficiently high titer.

4.6.5 Immunoelectrophoresis

Until replaced by immunofixation, immunoelectrophoresis was the method of choice. It can be credited with raising researcher awareness in the 1950s that serum proteins were an enormously complex family of moieties.[30] A sample is separated in a gel matrix, often on a microscope slide. Adjacent to this, and usually on both sides of each lane, antiserum is introduced into a narrow trench to diffuse laterally into the gel containing the sample. As antiserum and serum proteins diffuse passively towards each other, precipitates develop in the form of arcs. The location and configuration of the arcs (the result of p*I* in the particular system and the molecular weight of the serum protein) dictate where the precipitate forms; the radius of the individual arc is the result of molecular size and concentration (see Figure 10b). The major advantage was that the antigenic identity of the diffusing proteins could be assessed. The principal disadvantage, which eventually led to its replacement, was that the interpretation of the patterns was too often a matter of expert opinion. Artifacts are common and further tax the reader's abilities. Another useful feature of great assistance was that a very creative way could be devised to ascertain partial or complete identity of arcs: by the placement of addition wells, much as was done with simple immunodiffusion. As with all immunodiffusion methods, the potency of the antiserum and its specificity were paramount.

4.6.6 Immunoblotting

Firm binding of protein to membranes provides an efficient means of capturing proteins for subsequent reaction

with antibody or dyes. Several types of membranes are available, each with special characteristics: cellulose acetate, nitrocellulose, nylon, and polyvinylidene fluoride.[33]

Movement of the protein from the matrix to the membrane can be accomplished by simple diffusion aided by blotting papers. This technique is slow and results in some loss of resolution but its simplicity has advantages. A faster technique is to use an electric field: electroelution. The proteins are driven into a membrane with affinity for proteins and then identified by combining with labeled antibody or by direct staining, affording a powerful diagnostic tool analogous to immunofixation (see Figure 11b). Intact or dissociated proteins can be separated, and reagents that interfere with antibody reactions are removed from the membrane prior to reaction with antibody. Blotting can be done on high-resolution acrylamide systems that are not amenable to immunofixation, thus allowing detailed separation and rapid elution to an easily handled membrane.

A variation on this theme is checkerboard immunoblotting (see Figure 11a) where a membrane is exposed to several lanes of fluid, serum or antibody, created by a plastic form but without electrophoretic separation.[34] This step is followed by washing outside the slotted chamber and then its return to the chamber at right angles, where the slots are filled with a reactant: antibody or serum. Final washing and staining provides a qualitative assessment of each combination in the checkerboard

(a)

Figure 11 Two types of immunoblotting: (a) checkerboard immunoblot developed with several dilutions of patient serum and two purified antigens; (b) immunoblot transferred by electroelution after electrophoretic separation of a tissue homogenate and developed with patient sera (lanes 2 and 3), an eluate from a protein A column exposed to the patient shown in lane 2 (lane 4). Lane 1 contains molecular weight standards, electrophoresed and stained.

(b)

Figure 11 (*Continued*)

pattern. The method is particularly useful when multiple antibodies are to be used on single samples, or the converse.

4.6.7 Combinations

Great innovation and creativity have characterized investigation in electrophoretic methods. Combinations of methods, one after another, afford a separation power that taxes the workers' ability to understand the results. Only a few merit mention here, but many more can be found in the literature. The main enhancement has been the use of one method followed by a second, applied to all or part of the first separation. Two-dimensional electrophoresis is the most familiar (see Figure 12). In this modification, separation of a single sample along one axis by any of the above methods or in different matrices is completed. The strip is physically removed and applied in the second system, with electrodes rotated at 90°. If the first dimension is simply acrylamide or agarose

Figure 12 Two-dimensional immunoelectrophoresis in agarose gel. The first dimension was from right to left as a thin strip from the well. The second dimension was from bottom to top, from the strip into a gel containing high-quality anti-whole serum antiserum (Dakopatts). Each "rocket" represents the precipitate developed by one type of antibody and its respective antigen. Over 55 individual antigen–antibody pairs can be identified. Visualization is after washing and staining.

gel separation, the second could be isoelectric focusing, with the result that each apparently single band in the first dimension becomes a family of spots in the second phase. Results can be truly bewildering and interpretation difficult. Devices and protocols have become sufficiently precise to allow the results of different runs to be analyzed by flicker-fusion in the search for significant differences in the hundreds to thousands of spots. Materials to be analyzed can be soluble proteins, tissue extracts reduced with sodium dodecyl sulfate or culture fluids.

Much less sophisticated are combinations employing physical arrangements of sample and antibodies. Two-dimensional immunoelectrophoresis offered creative ways to demonstrate the antigenic identity of related proteins in a manner that was not possible otherwise.[35,36] These methods have largely been relegated to the archives but they may still answer difficult questions not otherwise addressable (see section 4.2.1.3).

5 PATIENT AND SAMPLE PREPARATION

The most elegant and precise assay can be no better than the least precise aspect of a procedure. Uncomfortably, the weakest aspects of every analysis come before and after the actual technological process. Failures at these levels can be so great as to swamp the results of the best analytical performance.[3] Laboratorians tend to forget that the preparation of the subject and the management of the sample itself present risks that can destroy the accuracy and precision of the measured result. To a lesser degree, the reagents are also subject to failure at the laboratory level, at the manufacturer or during shipment. All aspects can be monitored by properly designed quality-control measures but the patient is beyond our control, as will be described below.

All steps in the following sections can affect the final result, such that the most precise measurement can be rendered worthless at best or misleading at worst, by a series of extra-analytical events beyond the control of the measurer. These fall into three broad categories.

5.1 Preanalytical Requirements

The patient is advised to follow a protocol the evening and morning before phlebotomy. The steps are uncomplicated, but should the person or the physician's office staff ignore them, significant alterations in analyte levels can ensue. The request is that the patient follows the steps below:

1. *Have a "light" meal the evening before*. Briefly, this means a meal of modest fat content. A sample taken 1–2 h after a heavy meal may contain a significant amount of chylomicrons, which interfere with the analytical instrument.
2. *Avoid alcoholic beverages from 6 p.m. on the evening prior to the morning of the phlebotomy*. Certain patients may be very sensitive to alcohol-induced hyperlipemia.
3. *Do not smoke cigarettes on the morning of the phlebotomy*. The effects of cigarette smoke are not well understood and do affect certain protein levels.
4. *Drink only water the morning before; no stimulants, no breakfast*. This is for the same reason as in step 1.
5. *Take medications as usual*. If the medication has an effect, it will be long term and should be known to the physician.
6. *Do not engage in vigorous exercise immediately before phlebotomy*. Vigorous exercise can have a marked effect on certain serum proteins in the short term.
7. *Be seated at least 15 min before phlebotomy*. Equilibration of body water into and out of vascular spaces varies with position. Values for bedridden patients are very different from those of ambulatory subjects, but the differences are not usually appreciated.

8. *Use a tourniquet for only a short time and minimally applied*. Prolonged and excessive pressure can alter water content distal to the tourniquet.
9. *Do not shake the vacutainer after filling*. Shaking whole blood or clotted and separated tubes can produce mechanical hemolysis of red cells, which is more marked when red blood cells are already fragile.
10. *Avoid foaming of sample*. Foaming accelerates degradation of sensitive serum proteins.
11. *Cool sample as soon as possible*. Never freeze whole blood. Cooling slows protein degradation markedly. Freezing ruptures red blood cells.
12. *Pay attention to special sample requirements, e.g. anticoagulants, protease inhibitors, chelating agents, etc.* Certain proteins are very sensitive to degradation, and agents to preserve them are needed.
13. *Always mark tubes properly and as ''plasma'' if anticoagulated*. Anticoagulants, if added in liquid form, affect the final concentration as a result of dilution. Demographic information is critical to interpretation.

Each step can introduce analytical or interpretative problems that reduce the accuracy or ultimate meaning of the recovered value.[37] Of critical importance is to supply patient demographics such as age and gender, which affect the reference range against which the result will be compared. Other factors are unquestionably important but at present unknown, such as ethnic group, geography, diet or use of recreational drugs.

Once the sample has been drawn successfully, further care is required. The sample must be allowed to fully coagulate if serum is required. A sample that clots incompletely for any of a variety of reasons may remain on the verge of further clotting. Entry of an incompletely clotted sample into a testing device may result in a partially plugged probe and a reduced aspirated sample volume. In electrophoresis, unclotted or unclottable fibrinogen may mimic a monoclonal immunoglobulin. Once fully clotted, the sample is usually centrifuged to sediment suspended cells and debris. During this procedure the sample should be sealed to avoid desiccation. The device should be temperature controlled to avoid heating and accelerated degradation of sensitive proteins. In some laboratories special separatory tubes are used that do not require centrifugation, but these simple devices can damage cells or allow cells to bypass the plunger if too much pressure is applied. Separation of serum should be performed within 2 h of clotting to avoid release of cellular proteins, including hemoglobin.

Storage temperature is critical. If the samples are to be analyzed during the same working day they should be kept at near 4 °C. If not tested within 48 h the samples should be frozen at −20 °C. Tubes should be tightly capped in either case. During prolonged freezing the sample should fill the tube to more than two-thirds of its volume. If not, use a smaller container to avoid the problem of desiccation within the tube. For long-term storage, −70 °C should be used.

5.2 Intra-analytical Requirements

In laboratories where serum proteins are tested routinely by both quantitative and electrophoretic methods, the procedures should be performed in close proximity to one another. Preferably, the results of serum protein electrophoresis should be known before quantitative analysis is begun, to prevent serious errors as the result of unrecognized extreme elevation in the concentration of some proteins, with resulting antigen excess conditions. Failure can result in the reporting of incorrectly low or normal values when in fact the values are extremely elevated (see section 4.2.1).

Most other intra-analytical failures are approachable by regular use of controls and calibrants. However, there is one very serious situation that often defies monitoring despite the most rigorous training of staff: the mismarking or misinsertion of a sample, with the result that recovered values are attached to the wrong patient. A partial fix for this situation is noted above, where serum protein electrophoresis is available before the quantitative assay; thus, when the final results appear there is a rough check available. Automated bar-coded sample identification is a solution for some situations. However, in a more serious and uncontrollable situation the receipt of a mislabeled sample is irretrievable. It is hoped that the final step by the laboratory physician and the referring physician, upon seeing results that are at odds with clinical judgment, triggers repeat testing for confirmation. Samples that lack the specifics of proper label, name or demographics should be destroyed.

5.3 Postanalytical Requirements

Serum protein studies are usually performed in clusters and not as isolated measurements. Such lone values are virtually meaningless to the physician. In a like manner, the failure to supply patient information seriously compromises the final result and, although numbers are recovered, their clinical meaning is usually lost.[38] The availability of a suspected diagnosis or at least a complaint can increase the diagnostic value greatly. Obvious, but less well appreciated, is the conveying of associated test results such as protein polymorphism, serum description

(color and turbidity), autoantibody test results and the like, for the interpreting physician.

6 LIMITATIONS

The imprecision of reported values for a case will be: $\sqrt{\text{(individual errors)}^2}$. In addition, serum protein values are rarely valuable and useable as single numbers. They are generally analyzed as a cluster, each lending weight and credibility to the others. Possible exceptions are tumor markers, but here also abnormal values can be the result of noncancerous conditions, analytical failures and errors, as discussed above. Clinical use of superior results from carefully prepared patients must still face the rigors of interpretation in the setting of the particular subject.

6.1 Concentration

Alluded to above is the fact that values from patients after prolonged bed-rest can be quite different from the same person when ambulatory, even if no pathology has supervened. The shift of water from extra- to intravascular spaces can result in concentration shifts of as much as 15%. However, in most cases interpretation is carried out without that knowledge. A few workers over the past two decades have tried to address this issue by attempting to normalize values based on the level of oncotically active proteins in the serum sample. Although not ideal, it does mitigate the error induced in this way. Concentration variations as a result of variations in hydration are thus reduced.[38]

6.2 Secondary Factors

Final reported values can be altered by any of several factors either singly or in combination.

6.2.1 Interference

Certain assay techniques are more sensitive to interference than others. As noted above, the clarity of a sample can affect precision, hence the requirement that the patient fast prior to phlebotomy. In most subjects, serum is clearest after an overnight fast and, as a result, interfering chylomicrons are at a minimum. Older methods such as radial immunodiffusion can be performed on even extremely turbid samples and even on tissue extracts or homogenates.

Serum or plasma from some patients with serious autoimmune disease can have very high levels of immune complexes, which at times can produce a visible turbidity that may interfere with the assay systems. The most common cause of opacity, however, is the presence of chylomicrons, as the result of lipid intake before phlebotomy, inherent hyperlipemia or hyperlipoproteinemia. In some patients ingestion of alcohol will produce prolonged hyperlipemia. Administration of corticosteroids for disease control can also produce turbid samples of serum or plasma.

One of the requirements for test kit licensure by the FDA is that the manufacturer has tested the product to ascertain at what level an interfering substance will cause imprecision or inaccuracy. A wide variety of materials, from commonly used drugs to free hemoglobin and bile pigments, are examined. The immunoturbidimetric or immunonephelometric assays are very forgiving of interference by these substances. The sample size used for each assay type also has a significant effect. Assays for albumin or IgG, which use very small sample volumes, can be done on even turbid or hemolyzed samples, whereas assays for complement component C4 and C-reactive protein, which use relatively large sample sizes, are more affected. Heterogeneous ELISAs and RIAs also are largely unaffected by a host of substances that are eliminated from consideration by the washing steps.

6.2.2 Patient Demographics

For a value to be useful to the physician, it must be interpreted by a knowledgeable person or in the future by a capable ''expert system''. Virtually all tests must be interpreted in the light of as many pieces of demographic information as is available. As a result, the information about age and gender is absolutely essential. In time, additional population variables such as diet, medications, geography and ethnicity will also affect the meaning of a test result. Having said that, it must be recognized that once a population variable is thought to be important, reference ranges for that variable must be incorporated into the interpretation. At present, reference ranges for serum proteins covering age and gender are just beginning to appear.[39] In a more complex fashion, information about the individual case will become a crucial factor in extracting clinical meaning from laboratory results. The ideal reference interval in the future will be one based on the single patient's past values, adjusted for age.

6.2.3 Stearic Hindrance

In immunochemical assays, the reaction of the analyte with the antigen can be blunted or totally obliterated by a pre-existing immune reaction that has occurred in vivo. The most common situation is when a test for rheumatoid factor is found to be unreactive when a positive result is expected. In these cases, the IgM rheumatoid factor, which has specificity for altered IgG, appears to be

missing, as though normal. Called ''hidden'' rheumatoid factor, these molecules are partially or totally complexed with circulating altered IgG, thus failing to be detected by the altered IgG-covered reagent particles.

Anti-double-stranded-DNA testing can be converted to a positive reaction if there are anti-histone antibodies in the sample. Because DNA and histones have affinity for each other, the reaction can be mistaken as a true positive anti-double-stranded-DNA when in fact the sample contains free histones that have bound to the substrate DNA and will be recognized by anti-histone antibodies in the same sample. Anti-histone antibodies are induced by a wide variety of medications and do not have the same serious implications as does the presence of anti-double-stranded-DNA.

Many samples contain heterophil antibodies that can produce a positive reaction in a variety of tests. As the name implies, these are human antibodies that react with animal immunoglobulins used in immunological testing. They probably result from immunization in infancy against bovine immunoglobulins present in milk, rabbit proteins present in the diet of some areas and murine proteins seen in impoverished populations. These must be considered as potentially interfering in a significant number of immunological test methods. Examples are the mono-spot test for mononucleosis and other very sensitive immunoassays. Suitable controls are essential.

6.2.4 Dilution

6.2.4.1 Infusions At the time of phlebotomy, several situations can interfere with analyte concentration. Perhaps the most common is the inattention of the phlebotomist to the fact that the patient is being administered intravenous fluids in the limb from which the sample is being drawn.

Less obvious is the fact that the patient may have received infusions of plasma shortly before the sample is drawn. Because most serum proteins have a half-life of many hours or days, an administered unit of plasma or whole blood can significantly alter the true level of an analyte. This is particularly true for those proteins that may be at very low levels prior to samplings, e.g. IgA and complement components.

6.2.4.2 Post-transfusion Banked blood may at times be administered towards the end of the shelf-life of the unit and so red cells are not as robust as normal. As a result, administration of an ''old'' unit of cells may release the hemoglobin of a small fraction of the total, resulting in artifactual hemolysis with subsequent prompt removal of the hemoglobin–haptoglobin complexes thus formed. Five milliliters of lysed red cells will eliminate the total circulating mass of haptoglobin in less than 5 min. Although the administration of aging red cells may be uncommon in sophisticated institutions, it must be considered as a cause of ''hemolysis''. Prudence dictates that serum protein testing should be delayed until 48 h after the last transfusion is completed. It is of interest to appreciate that in vitro release of hemoglobin has little effect on haptoglobin levels because the complexes are still measured in the assay system, whereas in vivo release quickly reduces levels.

Since the blood volume of an average adult is in the neighborhood of 5 L, addition of one unit can affect the concentration by ~7–10%. At times, many units may be required over a short period with a major fraction of the blood volume having been administered. In these circumstances, drawing blood for serum protein levels is not advised.

6.2.5 Accelerated Catabolism In Vivo or Adsorption In Vitro

An analyte of interest may have been removed from the circulation in vivo or from the sample in vitro. In the first instance, intense immune complex formation can remove an analyte from the serum, although this should be viewed as part of the pathological process. A dramatic example is during intense immune complex formation in lupus erythematosus, where complement components are removed as the result of complex formation on glomerular basement membranes. Indeed, the lowered levels are diagnostic. The red cell membrane may also be the target of complement-dependent hemolytic activity.

Certain proteins such as fibronectin have affinity for glass and plastic surfaces, with the result that unless special precautions are taken a blood sample may have markedly reduced levels of such an analyte as the result of vigorous attachment to the inside of the sample tubes. In a very similar manner, antibodies that are temperature sensitive and have a high affinity for red cell membranes can be totally lost to analysis if precautions are not taken to maintain the sample at body temperature throughout the separation process. Cold agglutinins and cryoglobulins present at very high concentrations can be absent from a serum separated at room temperature.

6.2.6 Factitious

Factitious change due to adulteration of samples in an attempt to gain medical attention (Münchausen's syndrome) or to appear ''normal'' for insurance policy acceptance, although rare, is an important consideration. Such a situation was seen by both authors when urine samples sent for protein analysis yielded a very high value and an incredible level of glucose. Further investigation showed that the cause of these very abnormal values in an apparently normal child resulted from the mother, a nurse

in both cases, adding commercial meringue dessert mix to the child's urine sample, ostensibly to prevent the child from having to take part in physical education classes. Although this may be an extreme example, very abnormal results should always raise this issue for consideration. The substitution of another person's serum is, of course, undetectable unless suspicion is raised. Although much more common in drug testing programs, this does also occur in pre-insurance exam testing and should always be considered.

6.3 Proper Reference Ranges

If the laboratory does not use the proper reference ranges, interpretation of the final result will be incorrect[3] (see Figure 13). In addition to variables such as age and gender, several proteins exist as isoforms, each of which is found in the serum at different concentrations. Without knowing which isoform is present in a given patient, the measured value cannot be interpreted with certainty. An example is the measurement of α_1-antitrypsin, which is markedly affected by the genetic phenotype of the subject. At least 75 variants exist, as defined by isoelectric focusing. Only p*I* types MZ, MS, SS and ZZ result in levels that are detectably outside the reference range. These types are also detectable by standard agarose electrophoresis. Therefore, clinical interpretation of α_1-antitrypsin values must take into account the electrophoretic type. Low levels can be functionally normal for certain proteinase inhibitor types as long as total values exceed 0.50–0.60 g L^{-1}. Levels lower than this can lead to progressive damage to lung alveolar membranes from released leukocyte proteases that are uninhibited as a result of inadequate levels of α_1-antitrypsin (see section 4.5.9).

Figure 13 (a) Graphic representation of normal values for one serum protein (IgA) in females from birth to age 100 years. NB, newborn. The 5th, 50th and 95th centiles are shown. (b) Graphic demonstration of the differences in median serum IgM values between males and female during life. (Adapted from Ritchie and Navolotskaia.[3])

Because some serum proteins are influenced by commonplace situations such as pregnancy and use of contraceptive medications, interpreting these proteins should take this knowledge into consideration.

At present, authoritative specific reference ranges for ethnic groups other than Caucasians are unavailable, but such work is in process. Work in the 1960s revealed that Africans domiciled in the United Kingdom had higher immunoglobulin levels than Caucasians. This was also found in African–Americans in the southeastern USA compared to those living in the north.

6.4 Reference Materials and Calibrators

Until recently, serum protein reference materials were only loosely inter-related in spite of the existence of authoritative reference preparations in the possession of the World Health Organization (WHO), The Centers for Disease Control (CDC), the National Institute for Biological Standards and Controls (NIBSC), to name but a few. In 1994, as a result of awareness that there was no reference material consistency among manufacturers of serum protein assay, the International Federation for Clinical Chemistry (IFCC), with financial support from the Bureau de Référence Communitaire (BCR) in Brussels, produced a new certified reference material CRM 470[40] that was manufactured to the highest standards and is now distributed both in Europe by BCR and by the College of American Pathologists (CAP) in the USA. This material, designed for modern immunochemical analysis of serum proteins, is now being used worldwide with the result that interlaboratory harmonization is occurring, as demonstrated by several workers.

6.5 Other Effects

Although not appreciated as yet, a variety of other commonplace circumstances may ultimately be shown to have an effect on what constitutes expected reference ranges. Cigarette smoking has been shown to have a modest effect on IgG, and certain common medications suppress the acute-phase protein C-reactive protein while elevating levels of transthyretin. Other medications and even drugs of abuse may eventually be shown to have an effect. Diet type has a clear long-term effect on levels of lipoproteins, probably not directly but through the intermediary of obesity. Short-term effects of all these factors remain to be investigated.

7 QUALITY CONTROL

The goal of every conscientious laboratorian is to deliver the best and most clinically useful results possible. To achieve this within the confines of the laboratory itself requires that every step of the process be regarded as a pitfall and that ways are designed to uncover errors on a consistent basis[41] (Table 8). Although federal regulation mandates certain checks, each laboratory can add steps that provide a greater degree of certainty that the values that are delivered are of the highest quality.

7.1 Operational Checks

Recognizing that all modern assay methods rely on the stability of increasingly complex instruments and reagents places a requirement on the laboratory to be constantly alert for unforeseen changes. The failure of a system element – reagent or instrument – generally results in easily recognized, aberrant results. Failures of qualitative features are more overt and of quantitative features much less obvious. However, drift can result in gradual change that may be impossible to detect unless specific checks are inserted into every protocol and test run. For example, all illumination devices suffer gradual deterioration in output intensity. In a like manner, detectors also degrade slowly to a given signal strength.

Reagents themselves suffer equivalent degradation as a result of oxidation, denaturation, bacterial contamination or even photooxidation in the case of some fluorescent materials. Yet another source of operational failure is batch-to-batch variation and even vial-to-vial variation, all of which must be anticipated.

Within the reagent family reside calibrants and ultimately reference materials (see below). Often unappreciated by the clinical laboratory will be drift as a result of changes in the tested population, due to either the type of patient (age, gender or race) or the referral of subjects from the health care system itself. Finally, seasonal changes that can expose samples to extremes of temperature can result in accelerated degradation of some, but not all, analytes. Seasonal changes in reference values from a local population have been examined but with little effect noted.

Table 8 Recommendations for optimizing operational performance

- Measure illumination intensity (this may be accomplished automatically in some modern instruments)
- Measure detector performance, e.g. blank readings and baseline levels
- Discard reagents older than the recommended expiration date unless full revalidation is completed
- Do not mix reagent batches
- Aliquot bulk reagents into small, sealed containers
- Insert samples with known concentration values at several concentrations over the dynamic range (at least five)
- Insert samples at the beginning and end of a run whose concentration is known (and in the middle of the run if it is long). Select control samples at various concentrations and consider using occasional samples that are expected to force the system to fail or default to a ''no result'' mode
- Change parts at recommended intervals and never reuse cuvettes that have not been washed properly
- Perform basic quality checks on all purchased reagents regardless of confidence in the supplier

7.2 Dynamic Range

All quantitative assays perform best over a specified span of values: some methods over 10-fold from the minimum level of detection and others over 1000-fold. Called the dynamic range, the span dictates the ideal range for optimal assay performance. Superior performance can be expected toward the center of the range, whereas precision falls off towards the extremes. The degree of imprecision dictates what is the acceptable analytical range within which values can be trusted. Unfortunately, some laboratories attempt to modify assays by decreasing expensive reagent strength, such as antibody, or accepting values that fall near to, but outside, the recommended levels. For immunoassays the result will be that for low values the sample ''noise'' becomes a significant issue and truly undetectable levels will yield an erroneous value or, of more concern, values that fall above a specified level can be in error as a result of antigen excess conditions masking great elevations when recovered raw values exceed the threshold by a small degree. This is a major concern for the immunoglobulin assays, where instrument manufacturers have gone to great lengths to incorporate procedures that prevent a final answer if the value is too high. The operator must then reinsert a diluted sample or more antiserum and re-assay the sample. The instrument itself may do the equivalent without operator intervention. Immunoassays now perform to the same degree of precision/imprecision that can be expected from traditional colorimetric assays.

8 REGULATORY ISSUES

With serum protein testing worldwide having topped $4 billion, it is not surprising that competition is intense and the desire for profit climbs inexorably. With it has come an increasingly complex fabric of regulations that apply equally to the manufacturer and the laboratory. In addition, because the force that drives this commerce is

the physician ordering the tests, regulations are applied to their practices as well.

These regulations, although increasing costs at all levels, are absolutely necessary to protect the entire system, particularly the patient being tested. The result of regulation has been that products today are of greatly increased standardization and efficacy and the effort made by commercial companies in verifying their product claims has contributed significantly to the total medical knowledge base.

Many organizations play roles in stabilizing the laboratory worldwide. Perhaps best known is the WHO, which has shepherded the development and storage of reference materials for decades. Among them have been primary reference preparations for many serum proteins. In a like manner, the NIBSC in the UK and the National Institute for Standards and Technology (NIST) in the USA have contributed to the current excellent state of the art in reference materials. From a somewhat different perspective, the IFCC and the National Committee for Clinical Laboratory Standards (NCCLS) have provided initiatives for the onerous task of providing regulatory guidelines. From yet another aspect, that of quality assurance, CAP and other national quality assurance organizations have developed and executed programs that give all laboratories the means to assess, and correct if need be, their actual performance. The BCR of the European Communities has generously supported protein-related projects, one of which produced CRM 470. Finally, the United States FDA brought all these efforts to focus, at least in the USA, by providing a required framework in which industry, laboratories and professional societies must focus on the goal of providing quality products for the clinical laboratory and appropriate results for clinical use.

9 CLINICAL APPLICATIONS

Changes in the concentration, structure or function of proteins in plasma or other body fluids may be determined genetically and result directly in disease due to an abnormality or deficiency in a specific protein. More commonly, changes are secondary to a disease process affecting protein synthesis, distribution or catabolism. The laboratory methods for the investigation of plasma proteins are those of measurement, separation and characterization.[42–45]

Genetic variants, although not common individually, form an important group for the clinical laboratory to investigate because they are often essential for the diagnosis of a disease process. Secondary changes vary enormously in clinical usefulness; they may be pivotal to a diagnosis, such as the finding of a monoclonal component in myeloma, or simply be a part of the jigsaw of diagnostic information that allows us to assess the probability of a particular disease. In an increasing number of cases, sequential protein measurements are crucial in the monitoring of disease activity and response to treatment. More recently, the concept of triaging or sorting according to urgency, to allow rational use of expensive treatments, has become important in medicine. The plasma proteins, as sensitive markers of key processes such as inflammation, have an important and developing role in this field.

It is thus important that both qualitative and quantitative techniques are available in the laboratory. Plasma proteins fall into a series of functionally related groups, which makes it useful to define profiles of protein measurements to address pathophysiological issues. In many cases, alterations in molecular characteristics occur alongside changes in concentration, thus demanding the complementary use of separation and characterization techniques. Simple electrophoresis on cellulose acetate or agarose is a most useful tool providing a considerable amount of information that complements quantitative specific protein measurements. It also allows the identification of a number of genetic variants that result in changes in electrophoretic mobility. The identification of proteins separated by electrophoresis and by the use of immunofixation or immunoelectrophoresis, further increases the discriminatory power of qualitative examination.

For proteins present in plasma at concentrations above $1\,mg\,L^{-1}$, quantitation may be done by gel diffusion, electroimmunodiffusion, nephelometry and turbidimetry. Below this concentration, RIA and ELISA are the most widely used techniques. Functional assays are essential for proteins that are present in normal concentrations but whose function may be defective.

9.1 Study of Protein Polymorphism with Clinical Implications

Any large biological molecule can present variations definable by some technique, either chemical or functional, or by any method that will separate one isoform from another. For serum proteins, electrophoresis has been used for decades. For example, a serum protein with more than one phenotype is measured by at least one technique. For example, there are three major genetically controlled phenotypes of the iron-binding protein transferrin – a ''normal'' TfC, a fast mobility TfB, and a slow-form TfD – all of which have slightly different amino acid content. However, there are an additional 38 rare variants known. To demonstrate the various forms, high-resolution electrophoresis is required. If phenotype description includes alterations in molecular structure as

a result of nongenetic effects, additional forms can be identified for transferrin. The normal form of transferrin can be separated by isoelectric focusing into four isoforms appearing at p*I* 5.2, 5.4 (the major fraction), 5.6 and 5.7. Carbohydrate-deficient transferrin produced in high percentage (>1%) as the result of alcohol abuse can be separated into two bands at p*I* 5.7 and 5.9, the latter not being present in normal serum. In addition, transferrin in whatever form can bind one or two molecules of Fe^{3+} in the circulation. The iron-devoid form, apotransferrin, exists near the sites of iron incorporation in the gut and represents yet another form of the molecule.

This phenotypic division and subdivision of a single protein can be seen often among serum proteins. In certain circumstances the presence of a phenotypic variant leads to overt clinical disease directly, whereas in other circumstances disease results as an indirect consequence of inadequate or dysfunctional synthesis of the variant protein. An example of disease resulting directly from overproduction of an apparently normal protein, IgM, is Waldenström's macroglobulinemia. Normal levels are in the 0.4–3 g L^{-1} range in adults but, when a malignancy of IgM B-lymphocytes exists, synthesis can reach extreme levels. This protein with an M_r of 97 000 Da can reach 60–100 g L^{-1}, producing hyperviscosity, sludgeing in small vessels and resultant cyanosis, seizures, chest pain, poor lung perfusion, neuropathy, etc. A very large number of diseases result from the failure of specific protein synthesis. It is beyond the scope of this chapter to discuss even a limited number, but a few examples are listed in Table 9.

9.1.1 Example: Waldenström's Macroglobulinemia

Case history An 83-year-old, apparently healthy, elderly physics professor came to his local physician with a history that dated to the previous winter, of bluish discoloration of the tip of his nose, fingers and toes and the pinnae of both ears, on being out of doors. The discoloration had not been noticed during the warm months. This gentleman offered the opinion that "something is making my blood thick in the cold".

The physical examination revealed little except some palor and some scaring of the tip of his nose. He was otherwise well nourished, alert and without complaint. His entire physical examination was otherwise unremarkable.

His laboratory examination, however, provided many abnormal findings. The man's chilled blood, before the serum was separated, was noted to contain gelatinous strands that disappeared on warming. After centrifugation at room temperature the serum was clear yellow and unremarkable. The sample was then refrigerated routinely to await analysis. Two hours later, the sample was removed in preparation for transfer to a chemistry autoanalyzer. The technologist noted that the sample had separated into two phases, as shown in Figure 7. Placing the sample in a water bath at 37 °C cleared it and the tests were performed without difficulty. One of the tests run later was serum protein electrophoresis, which showed a very large, dense protein band in the region of the application point and an apparent precipitate that could be removed easily from the surface. Subsequent measurement of immunoglobulins revealed that the IgG level was at the 20th centile, IgA at the 26th centile and IgM was 35 g L^{-1} (about 35 times normal). Other chemistries were unremarkable. His red cell smear showed marked aggregation of red cells into chains, called rouleaux, and the red cells were hypochromic. A urine sample was found to contain a very large amount of protein, which later proved to be free monoclonal light chains (Bence Jones protein) of the kappa type. Immunofixation electrophoresis confirmed the band and the gel seen in the chilled tube to be monoclonal IgM of the kappa type as well.

His electrocardiogram showed some evidence of ischemia and the chest X-ray showed prominent pulmonary marking throughout. A careful re-examination of his optic fundi revealed mild evidence of segmenting of the blood column in the retinal vessels. His diagnosis was Waldenström's macroglobulinemia. His bone marrow aspirate was not remarkable, with the exception of a

Table 9 List of some phenotype-related diseases

Protein	Disease	Pathology
Failure of synthesis of lipoprotein AI	Tangier disease	Xanthomatosis
Overproduction of lipoprotein B100	Arteriosclerotic disease	Myocardial infarction
Synthetic failure of immunoglobulins	Immune deficiencies	Infection
Synthetic failure of complement factors	C3 deficiency	Infection
Dysfunctional ceruloplasmin	Wilson's disease	Liver and neurological disease
Failure of haptoglobin synthesis	Cholelithiasis	Excess bilirubin excretion
Diminished synthesis of transthyretin		Diminished ability to bind T3 and T4
Hypomorphic forms of α_1-antitrypsin	Emphysema, cirrhosis	Progressive lung disease in certain homozygous states
Failure of synthesis of blood clotting factors	Von Willebrand's disease, etc.	Bleeding diatheses

slight increase in mature lymphocytes. The patient refused chemotherapy of any sort, but agreed to return visits.

Four months later he returned, having been brought to the office at the insistence of a family member. The history now included bouts of disorientation, shortness of breath and weakness. Physical examination revealed that blood flow in the retinal vessels was interrupted by segments of clear plasma, his respirations were rapid and he was clearly disoriented as to time, person and place. An electrocardiogram showed evidence of myocardial ischemia and a chest X-ray showed more marked dilatation of the small pulmonary vessels.

Repeat laboratory examination revealed that his IgM level had risen to $60\,g\,L^{-1}$. He was now showing signs of renal failure, reduced pulmonary perfusion resulting in shortness of breath, early congestive heart failure and myocardial ischemia, poor cerebral perfusion resulting in disorientation and confusion and worsening of his cold sensitivity. The unusual fundoscopic finding of segmented blood flow was also the result of sludgeing. It was clear that all these physical features were being caused by increased blood viscosity as a result of the very high levels of the large immunoglobulin IgM (molecular weight 971 kDa). He was plasmaphoresed of 4 units over 24 h (removal of plasma) to rapidly reduce his blood viscosity and to prevent clinical collapse. After removal of the 4 units, all his acute symptoms cleared. He was then started on a program of chemotherapy to reduce the neoplastic cell mass responsible for the massive production of the macroglobulin.

GLOSSARY

The definitions for this glossary come from a glossary produced by the NCCLS,[46] the OVID Technology Medline Database and miscellaneous textbooks. The form in which it is presented is taken directly from Ritchie and Navolotskaia,[3] with permission.

Accuracy	The nearness of a measurement to its accepted or true value.
Agglutination	The clumping of cells, microorganisms, and so forth, caused by antibody or other natural or synthetic chemical factors.
Amino acids	Simple nitrogenous organic compounds that constitute all peptides, polypeptides and proteins.
Analyte	The substance, a set of substances, or ''factor'' to be assayed.
Antibody	A glycoprotein that is produced by B cells in response to exposure to an antigen and reacts specifically with that antigen; a part of humoral immunity.
Antibody diversity	The phenomenon of immense variability characteristic of an antibody, which enables the immune system to react specifically against unlimited antigens and is generated by the rearrangement of variable-region gene segments during the differentiation of antibody-producing cells.
Antibody specificity	The property of antibodies that enables them to react with some antigen determinants and not with others.
Antigen	A substance that is capable, under appropriate conditions, of inducing a specific immune response and of reacting with the product of that response (antibody or specifically sensitized T lymphocyte).
Antiserum	A serum containing antibodies.
Autoantibody	An antibody directed against a self-antigen, i.e. against a normal tissue constituent.
Biantennary	A chemical structure including two major arms.
B Lymphocytes	The bone-marrow-derived lymphocytes that are defined by the presence of endogenously produced immunoglobulins; a part of humoral immunity
Calibrator	A material of known characteristics (concentration, activity, reactivity) used to calibrate or adjust a measurement procedure or to compare the response obtained with the test specimen. The material must be of the same performance characteristics and can be used to standardize field methods.
Cathode	Negatively charged pole in electrophoresis.

Chaotrope	A substance that promotes dissociation of immunological complexes with minimal damage to the constituents.
Cytokine	Nonantibody protein, secreted by inflammatory leukocytes and some non-leukocytic cells, that acts as intercellular mediator.
Denaturation	Loss of the native configuration of the macromolecule, usually with resulting loss of biological or immunological reactivity or solubility.
DNA	Deoxyribonucleic acid, the principal chemical structure of heredity. Composed of ribose phosphate units in various combinations.
Electroendosmosis	Migration of buffers as the result of the presence of charged groups on the fixed matrix. The result is the flow of fluid rather than the charged particles that are anchored, e.g. agarose or cellulose acetate.
Electroimmunoassay	An immunoassay where antigen and antibody are forced into association, e.g. ''rocket immunoassay'' or ''electroimmunodiffusion''.
Electrophoresis, agarose	A form of electrophoresis in which protein molecules move through buffer suspended in an agarose gel matrix.
Electrophoresis, cellulose acetate	A form of electrophoresis in which protein molecules move through buffer suspended in a cellulose acetate matrix.
Electrophoretic mobility	A number that describes the movement of a protein in an electric field, usually in pH 8.6 barbital buffer of given ionic strength. The term can also be qualitative, e.g. α-, β-, γ-, etc.
ELISA	ELISA – an immunoassay utilizing an antibody labeled with an enzyme marker. The change in enzyme activity as a result of the enzyme–antibody–antigen reaction is proportional to the concentration of the antigen and can be measured.
Epitopes	The sites either on or within the antigen with which antibodies and T-cell receptors react.
Fab region	Fragment antigen-binding region of immunoglobulin molecule that contains an entire L-chain and amino-terminal half of the H-chain and is responsible for binding to the antigen.
False negativity	Negativity in a diagnostic or screening test performed on a specimen from an individual having the disease that the test is designed to detect.
False positivity	Positivity in a diagnostic or screening test performed on a specimen from an individual not having the disease, or other finding, that the test is designed to detect.
Genetic variant	A variation in a single molecular species that is defined by heredity.
Genotype	The genetic constitution of the individual.
Hemolysis	Disruption of the integrity of the red cell membrane, causing release of hemoglobin.
Heterozygote	A condition where two or more alleles exist at one genetic locus.
Immune complexes	The complexes formed by the binding of antigen and antibody molecules.
Immunoblotting	Immunological method for isolating and semi-quantitatively measuring immunoreactive substances.
Immunodiffusion	Technique involving the diffusion of antigen or antibody through a semisolid medium, usually agar or agarose gel.
Immunofixation	Method of precipitating an electrophoresed protein in an electrophoretic matrix.
Immunofluorescence microscopy	Microscopy of specimens stained with fluorescent dye bound to an antibody or antigen that emit light when

	exposed to ultraviolet or blue light.
Isoelectric focusing	Electrophoresis in which a pH gradient is established in a gel medium allowing proteins to migrate until they reach the site at which the pH is equal to their p*I*.
Isoelectric point (p*I*)	The pH at which the protein has a net charge of zero.
Isoform	One of several usually genetically determined forms of a single protein having the same antigenic structure yet differing in amino acid or carbohydrate content or configuration.
Isotachophoresis	Electrophoresis in which a pH gradient is established in a gel allowing proteins to migrate until they reach the zone at which their p*I* prevents further migration.
L (light)-Chains	The shorter polypeptide chain of the immunoglobulin molecule.
Microheterogeneity	Defines different forms of the same molecular species that are evident after special treatment.
Monoclonal antibodies	Antibodies produced in vitro by a cell line arising from a single cell. All molecules will be of a single class and subclass and with a single antigenic specificity.
Multiple myeloma	A malignant tumor of plasma cells usually arising in the bone marrow.
Nephelometry	A means of analyzing the amount of material in suspension in an optically clear fluid, by measuring the amount of light reflected from the suspended particles.
Phenotype	The end result of both the genetic and environmental factors giving the identifiable structural and functional characteristics of an organism or a protein.
pH Gradient	A system of buffers that create a controlled change in pH in an electrophoretic separation medium, e.g. agarose, polyacrylamide gel, hydrolyzed starch. The slope of change can be gradual, linear, discontinuous, etc.
Plasma cell	The type of mature B cell that actively secretes large amounts of a specific antibody.
Polymerization	The formation of a large molecule from identical smaller units.
Polymorphism	The condition in which a protein species exists in different forms.
Polypeptide	A substance composed of two or more peptides.
Precision	The extent to which replicate analyses of a sample agree with each other; usually expressed as imprecision (the coefficient of variation of a population of values, equal to the standard deviation divided by the mean).
Proteinase	A class of enzymes that split peptide bonds to form simpler compounds.
Proteinase inhibitor	A protein or other chemical that is capable of blocking the digestive enzymatic activity of a proteinase.
Radioimmunoassay	A quantitative assay for the detection of antigen–antibody reactions using a radioactively labeled substance to measure the binding of the unlabeled substance to a specific antibody or other receptor system.
Reference material	A material or substance in which one or more properties are sufficiently well established for use in calibrating or verifying a measurement, method or apparatus.
Reference values	The range or frequency distribution of a measurement in a population.
Rheumatoid factor	Antibody directed against antigenic determinant in the Fc region of IgG.
Sensitivity	A measure of the probability of correctly diagnosing a condition (for

	assessing the results of diagnostic and screening tests).
Specificity	A measure of the probability of correctly identifying a nondiseased person (for assessing the results of diagnostic and screening tests).
Steric hindrance	Interference based upon shape or proximity of adjacent structures.
Triantennary	A chemical structure including three major arms.
Turbidimetry	A means of analyzing the amount of material in suspension in an optically clear solution, by means of measuring the amount or percentage of light that passes through a given suspension of material.
Waldenström's macroglobulinemia	A malignant neoplasm of cells with lymphocytic, plasmacytic, or intermediate morphology that secrete an IgM component.

The importance of reporting quality patient results by clinical laboratories cannot be overstated. Maintaining and improving the quality of laboratory results is a never-ending process, and the thoughtful application of statistical quality control techniques is the key to this continuous pursuit. Using statistical methods, laboratories can ensure that their patient results are reliable and can continue to improve their performance.

It is clear that the method for monitoring quality control in the clinical laboratory will have a direct impact on the results reported by the laboratory. This article reviews the historical development of clinical quality control and details methods traditionally applied in the field. Recently proposed approaches are identified and their statistical performance is evaluated. Quality control methods involving clinical significance are also described, and economic modeling applicable to clinical quality control is presented.

1 INTRODUCTION

One of the most important aspects of diagnostic testing in a clinical laboratory is maintaining the quality of the results being reported by the laboratory. Since the reported results are used by physicians and pathologists to diagnose patient conditions and monitor patient progress, the quality of the results is of utmost importance. Therefore, quality control and assurance efforts regarding these results must be well planned and effective.

For many years, control materials have been tested and monitored to ensure the continued high quality of the patient results reported. These controls are stable materials of known (or assumed known) concentrations tested in the same fashion as patient samples, and they serve the purpose of evaluating testing system performance. The assumption is that changes detected by control materials will also impact on patient test results accordingly.

It is clear that the method for monitoring quality control in the clinical laboratory will have a direct impact on the results reported by the laboratory. This article reviews the historical development of clinical quality control and details methods traditionally applied in the field. Recently proposed approaches are identified and their statistical performance is evaluated. Quality control methods involving clinical significance are also described, and economic modeling applicable to clinical quality control is presented.

2 HISTORICAL DEVELOPMENT

The original application of statistical methods for monitoring quality control in the clinical laboratory dates back to the early 1950s.[1] In this original application, Levey and Jennings applied a Shewhart chart from industrial quality control and used average and range charts for subgroups of size two. Laboratory personnel today often refer to plots of quality control values as Levey–Jennings charts, but they are typically referring to charts of individual values plotted on a chart with limits set at ± 2 standard deviations (SD). This evolution from the original Levey–Jennings application of average charts to charts of individual values with ± 2 SD limits occurred gradually. Henry and Segalove's paper[2] discusses the plotting of single replicates against ± 2 SD limits, and the approach gained popularity in laboratories owing to its ease of use.

This evolution of quality control systems began in the 1950s and continues in many instances today. Typical approaches for monitoring controls in the clinical laboratory use three different levels of control materials (low, medium, and high) with targeted concentrations

across the measurement range of the diagnostic test. Each of these levels is tracked separately with control limits often placed at ±2 SD limits and applied to individual observations. Linnet's work[3,4] advocates averaging replicate observations of control values for monitoring quality control materials and shows the increased power of such an approach, but laboratory personnel have not embraced the practice.

In the late 1970s, Westgard et al.[5] published the first article assessing the statistical performance characteristics of clinical quality control methods. Using computer simulation, their work develops power curves for various combinations of runs rules. The graphs display the probability of detecting specific errors as a function of the number of control observations evaluated. The graphs are based on the probability of detecting a true error (p_{ed}) and the probability of a false rejection (p_{fr}). Additionally, the article discusses the concepts of random error (RE) and systematic error (SE). RE is the inherent imprecision, or noise, that a testing system will experience in a state of statistical control (SOSC). An SE is a change in the centering of the measurement system. Therefore, a change in the RE is a change in the measurement system variability, and an SE represents a change in the centering of the measurement system.

This work by Westgard et al. is extremely important as it set the direction for future evaluation of quality control approaches. The use of simulation became standard, and future models assumed a common shift to all levels used for monitoring. These assumptions, therefore, set the stage for work continuing into the 1990s.

Westgard et al.[6] used the developments of power curves to evaluate and propose a monitoring method combining a Shewhart control chart with a cumulative sum chart. While the approach performs well statistically, the sophistication of the method makes it unattractive to users and it has not been widely implemented.

Continuing the use of computer simulation to evaluate control methods comprised of combinations of control rules, Westgard and Groth[7] published what they termed "power function graphs". The graphs are refinements of earlier power curves, displaying probabilities of error detection and false rejection versus shifts in centering (ΔSE) and spread (ΔRE). These power function graphs provide a means for assessing a control monitoring system's performance and determining the statistical acceptability of a given approach.

3 QUALITY ASSURANCE VERSUS QUALITY CONTROL

A general distinction between quality assurance and quality control in the clinical laboratory must be made. As a rule, quality control refers to the internal assessment of control material testing. Alternatively, quality assurance often refers to larger scale activities and external assessments. Such external assessments are initiated by organizations such as the College of American Pathologists (CAP) or local regulatory bodies. In these quality assurance surveys, samples of unknown concentrations are tested at individual laboratories and their results reported to the governing body. Results across laboratories are compared to identify laboratories which are not producing results in agreement with the other laboratories participating in the survey. In contrast, quality control focuses on the internal assessment of control data and works towards continuous improvement of the testing system. It is clear that the results achieved through quality control will have a dramatic effect on the level of quality assurance evidenced by the laboratory through the independent survey assessments.

This article focuses on the issues and various approaches for applying quality control in the clinical laboratory. It is evident that a variety of factors must be considered when selecting the appropriate quality control approach for a given laboratory. A great deal of freedom is provided to laboratories in their selection since the Clinical Laboratory Improvement Amendments of 1988 (CLIA 88)[8] require that two levels of control material must be run each 24-h period. Within these general requirements, there are a variety of options available to clinicians for achieving quality control of their testing system. Determining the best approach for a given laboratory essentially consists of assessing the statistical performance, ease of use and implementation, and economic implications of the method selected. Given the proliferation of computer support available for analyzing quality control data, the options for clinicians continue to increase, and educated decisions regarding the selection of a quality control approach are definitely required.

4 TRADITIONAL STATISTICAL QUALITY CONTROL APPROACHES

A detailed review of the literature reveals that a large number of quality control approaches are available for application to clinical quality control. A few methods, however, have proven to stand the test of time and become the most common approaches in practice. These common methods include the strict application of ±2 SD limits (described in a previous section), the use of the Westgard Multirule Procedure (WR), or some subset of the WR. The following sections describe the WR and other sets of runs rules commonly encountered in practice.

4.1 Westgard's Multirule Procedure

Clinical Chemistry published the culmination of Westgard et al.'s work in the late 1970s and early 1980s as a ''selected method''.[9] Termed the ''Multirule Procedure'', Westgard et al. describe a combination of control rules to apply to monitoring control materials. The WR works as follows:

Reject if:

one point outside ±3 SD limits (1_{3s})

If one point outside ±2 SD limits, then consider:

(a) two consecutive points outside ±2 SD on the same side of the centerline (2_{2s});
(b) range of two points greater than 4 SD (R_{4s});
(c) four consecutive points outside ±1 SD limits on the same side of the centerline (4_{1s});
(d) 10 consecutive points above or below the mean (10_x).

As described in the original publication, all of the rules are applied both within a level of control material and across levels of control material. Suppose a laboratory is using two levels of control material (medium and high concentrations) for quality monitoring purposes. The 2_{2s} rule could be violated in two different ways. The first possible violation would be for both the medium and high control to plot outside ±2 SD limits on the same side of the mean on the same analytical run. The 2_{2s} rule would also be violated if the medium control plotted outside ±2 SD limits on the same side of the mean in two consecutive analytical runs. The result is that application of the WR as originally published results in a large number of comparisons which must be made in practice.

Although many clinicians endorse the procedure, there is still considerable confusion about its application in laboratories. The method can be difficult to implement manually as there are many comparisons required; many laboratories which claim to be using the WR are probably using some variation of the approach rather than the procedure as originally published.

Westgard et al. continued their work in the area of clinical quality control with the development of selection grids for planning quality control procedures.[10] The grids are tools which allow a user to select a set of control rules for a given application. The parameters for selecting the set of rules are the true frequency of actual errors in the laboratory and the critical systematic shift (ΔSE_c) that the user wishes to detect. Based on these parameters, the user can determine the number of replicates of controls to run and the control rules to employ.

4.2 Various Runs Rule Combinations

Following the appearance of the WR, there continued to be publication of other combinations of runs rules. Blum[11] published a method that incorporates the use of 10 different runs rules, justifying the selected rules using computer simulation. The method has not been widely implemented in the laboratory setting, probably a result of the complexity of applying the proposed runs rules.

A common practice of clinicians is to adjust the WR to fit their application. Certain runs rules in the procedure (primarily the 4_{1s} and 10_x rules) are sometimes ''turned off'' or dropped from the procedure because they tend to take longer to detect shifts in the process and often detect shifts that are relatively small in magnitude.

Another popular approach to monitoring quality control in the clinical laboratory is the use of ±2 SD limits verified by a retest. Since a number of laboratory personnel are aware that ±2 SD limits strictly applied will result in a high rate of false rejection, they choose to give the measurement system a ''second chance''. If the clinician tests controls and a replicate is outside ±2 SD limits, then the clinician reruns the controls and classifies the measurement system as unstable only if a replicate exceeds ±2 SD limits on the second run. If all control values are within ±2 SD limits on the second run, then the measurement system is considered stable.

5 RECENTLY PROPOSED CLINICAL QUALITY CONTROL APPROACHES

Recent developments in the field of clinical quality control have proposed new approaches to monitoring clinical quality control data. These methods are more sophisticated than some of the traditional methods which have been employed, but the availability of computer support for these new methods allows for their implementation in clinical laboratories. The option of implementing these more sophisticated methods on a real-time basis has not been available until the last few years.

5.1 Exponentially Weighted Moving Average Charts

In the spirit of improving the sensitivity of statistical quality control methods, Neubauer[12] recently proposed the use of the exponentially weighted moving average (EWMA) chart for application in clinical laboratories. The method has received attention for application in other industries[13,14] for some time and shown promising performance.

Application of the EWMA chart is relatively straightforward. A statistic is continually updated as new data are collected, and this statistic is plotted against control

limits. The statistic of interest, $EWMA_t$, is determined as follows in Equation (1):

$$EWMA_t = (1 - \lambda)EWMA_{t-1} + \lambda y_t \quad (1)$$

where t = time point, λ = weighting parameter ($0 < \lambda \leq 1$) and y_t = actual testing observation value. The parameter λ is used as a weighting factor to control how much emphasis is placed on recent data. The larger the value of λ, the more weight is placed on recent data. For example, setting λ to 1.0 would be the same as plotting the actual data themselves.

The selection of λ is a necessary decision when using the EWMA chart, and it is clear that its selection will impact the variability seen in the EWMA statistic. Larger values of λ will result in more variability, but the resulting control limits will also be more responsive to changes in the mean of the measurement process. Therefore, selection of λ is a tradeoff between reducing variability in the plotted statistic while at the same time adequately representing recent data in the statistic. Typical values of λ range between 0.05 and 0.25.

5.2 Multivariate Approaches

Another approach to statistical quality control in the clinical laboratory capitalizes on the inherent multivariate nature of clinical laboratory quality monitoring.[15] Multiple levels of control materials are typically tested at the same time when monitoring quality control. This results in a natural correlation among the control materials being monitored. Testing variation in clinical laboratories is generally largest from run to run with the sources of variability including environmental variability, technician variability, variation within the instrument, and materials variation. When the quality control levels are tested side by side, they are all affected by essentially the same run to run variation. This creates correlation among the levels. The correlation, however, is not perfect as there are some sources of variation that can affect individual levels differently. However, a positive correlation among control material testing data is fairly common.

While there are a number of multivariate approaches available for quality monitoring, the χ^2 chart is an attractive candidate owing to its relative ease of use. The χ^2 chart allows for the simultaneous control of p quality characteristics. For the clinical application, the number of characteristics, p, will correspond to the number of control levels being monitored. For the quality control application to multiple quality characteristics, one can test the hypothesis that $\boldsymbol{\mu} = \boldsymbol{\mu}_0$ where $\boldsymbol{\mu}_0$ is a specified vector (the historical mean vector of the control level data). The critical region to test this hypothesis is $j(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)\boldsymbol{\Sigma}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0) > \chi^2_p(\alpha)$, where j is the sample size (in the clinical application, $j = 1$), p is the number of characteristics being monitored ($p = 2$ or 3 control levels for the clinical case), α is the type I error associated with the chart, and $\bar{\mathbf{x}}$ is the observed sample mean vector.

The assumptions underlying the application of the χ^2 chart (besides that of multivariate normality) are that the specified mean vector ($\boldsymbol{\mu}_0$) and covariance matrix ($\boldsymbol{\Sigma}$) are known. While theoretically impractical, these assumptions may be applied in cases where a great deal of data has been collected surrounding the diagnostic measurement system.

In some instances, the assumption of a known mean vector and covariance matrix are not supportable, resulting in the requirement of another approach instead of the χ^2 chart. Such an approach is the T^2 chart, which assumes an unknown covariance structure and an unknown mean vector. Developed by Hotelling,[16,17] the T^2 statistic allows one to apply a multivariate control monitoring approach to p characteristics when the covariance matrix is unknown.

In all respects with the exception of the unknown covariance matrix and the mean vector, the T^2 chart is completely analogous to the χ^2 chart. As the number of subgroups used in establishing the T^2 chart limits increases to infinity, the T^2 chart will approach the χ^2 chart. Therefore, the question arises as to how many subgroups need to be collected to provide reliable T^2 chart limits. Additionally, how many subgroups are necessary before the T^2 chart can be effectively replaced with the χ^2 chart?

Similarly to the χ^2 chart, Anderson[18] showed that the T^2 statistic is defined according to Equation (2):

$$T^2 = m(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)'\mathbf{S}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0) \quad (2)$$

where $\mathbf{S}$ is the sample covariance matrix, m is the number of subgroups of size j collected, $\bar{\mathbf{x}}$ is the mean vector of the sample with dimension p, and $\boldsymbol{\mu}_0$ is the historical mean vector. The upper limit for the T^2 chart is calculated as shown in Equation (3):

$$\text{upper limit} = \frac{(m-1)p}{m-p}F_{p,m-p,\alpha} \quad (3)$$

The effect of the number of subgroups on the control limits of the T^2 chart can easily be evaluated. Setting the α level for the T^2 chart at 0.01, Figure 1 shows the impact of the number of subgroups collected on the performance of the T^2 chart when a 2.0 SD shift occurs across all three levels of control material. Three different correlation coefficients (0.80, 0.50, and 0.10) among the three levels of controls are evaluated. This graphic indicates that there is diminishing return in increasing the number of subgroups collected for establishing the T^2 chart limits past 20 and that the correlation structure has little effect on the selection of the number of subgroups collected. The

Figure 1 Number of subgroups comparison for the T^2 chart.

graph also illustrates that the χ^2 chart can be effectively substituted for the T^2 chart with little loss of performance following a relatively small number of subgroups.

6 EVALUATION OF CLINICAL QUALITY CONTROL PERFORMANCE

Given the proliferation of approaches available for clinical quality control, it is necessary to select among the options based on objective criteria. Of primary importance is the statistical performance of the methods. Based on their abilities to avoid false rejections and detect true changes of importance in the testing system, the appropriate method can be selected for application. One of the difficult aspects of selecting the quality control method is that the two keys to statistical performance (i.e. avoiding false rejections and detecting true system changes) are difficult to satisfy simultaneously. Typically, methods which are very sensitive to system changes also have high false rejection rates. Conversely, methods with low false rejection rates may often be insensitive to changes in the measurement system. Evaluation of the statistical performance of proposed methods is of the utmost importance.

In order to evaluate the statistical performance of quality control approaches, researchers often use computer simulation models. There has been a great deal published in the clinical literature concerning the computer simulations used for this work, and the editorial by Westgard[19] provides an excellent summary of the assumptions employed in the simulators and lists many of these simulations. Hatjimihail[20] and Parvin[21,22] provide examples of recent simulation efforts. The literature also contains other approaches including neural networks[23] and genetic algorithms.[24]

Analytical approaches to analyzing control methods utilizing runs rules have been limited in the clinical laboratory literature until recently. Parvin[25] performed some analytical analysis by looking at data within a run, but his results are not widely applicable. Bishop and Nix[26] were the first authors in the clinical chemistry literature to obtain analytical results by applying Markov chains to procedures incorporating runs rules. Using Markov modeling to analyze the Westgard Rules as previously published, their work compares their results with previous computer simulation analysis. Bishop and Nix also proposed the use of a cumulative sum chart for monitoring control levels and provide results supporting its utility.

Lee[27] has also done some analytical work regarding the use of the WR. The sample sizes investigated by Lee were indicative of those actually implemented in practice, and his results provide good insight into the workings of modified approaches to the WR (i.e. not including the R_{4s} rule or using ± 2 SD limits as a screening criterion).

The methods discussed in this article can be evaluated and compared on a statistical basis. These methods include the strict application of ± 2 SD limits (2 SD), the use of ± 2 standard deviation limits with a retest (SD/RT), the original description of the WR, the χ^2 chart, and the EWMA chart.

Comparison of the quality control approaches is achieved through the average run length (ARL) of the approaches. The ARL is the expected number of test points before a quality control approach will signal. In other words, the number of times control materials must be evaluated (on average) before the quality control method indicates that there has been a change in measurement system performance. When evaluating methods that incorporate runs rules, it is important to evaluate their performance based on ARLs. For instance, adding the 4_{1s} rule does not affect the probability of detecting a shift in the first quality control sample taken after the shift, but it does reduce the number of sampling points required to detect the shift in the long run. For methods with a readily defined probability of detection, the ARL is simply the inverse of the probability of detection.

Using the ARL concept, the previously described quality control approaches can be readily evaluated from a statistical perspective. For the 2 SD, 2 SD/RT, and χ^2 chart approaches, probabilities of detection can readily be calculated analytically. Simulation results are used for assessing both the WR and the EWMA chart. For the χ^2 and EWMA charts, certain assumptions or parameter settings are necessary. This comparison sets the in-control ARL for both methods at 100 (i.e. a 1% chance of a false

rejection). Additionally, the covariance structure for the χ^2 chart must be specified, and it is fixed at a correlation of 0.50 (i.e. moderate correlation among levels). For the EWMA chart, a weighting factor, λ, of 0.20 is assumed.

For comparison purposes, it is assumed that two levels of control material are being monitored and that the same relative magnitude of shift is applied to both levels. ARLs are plotted as a function of shifts in the mean of the measurement process where these shifts are represented in multiples of the process SD (i.e. a 0.8 SD shift, etc.). The ARLs for the methods are shown in Figure 2.

From an examination of Figure 2, a number of conclusions are available. The first is the unacceptably low in-control ARL for the 2 SD approach. Laboratories employing this approach will incur a large number of false rejections, potentially leading to distrust of the quality control approach. This false rejection issue is alleviated through the use of a retest, and the long in-control ARL for 2 SD/RT is evidenced in the figure. The WR succeeds in reducing the false rejection rate incurred by the strict use of 2 SD limits and is more sensitive to shifts than the use of 2 SD with a retest.

Performance of the recently proposed methods of clinical quality control can also be evaluated using Figure 2. The EWMA chart has an attractive performance owing to the relatively long in-control ARL, but is also sensitive to true changes in the measurement system. Additionally, the χ^2 chart shows a good in-control ARL, but relative insensitivity to true shifts in the measurement process. As indicated by Dechert and Case,[15] the sensitivity of the multivariate approach is affected by the nature of the shift incurred, thus resulting in the relative insensitivity for the constant shift assumed here across both levels of control materials.

Finally, Figure 2 indicates that large shifts (i.e. shifts greater than 1.5 SD) are essentially detected equivalently by all of the methods considered. Hence if a laboratory is only concerned with detecting large shifts in the measurement process, any of the methods would be acceptable from an error detection perspective. Consideration of the associated false rejection rate would also be required.

Figure 2 Statistical comparison of quality control approaches.

7 CLINICAL SIGNIFICANCE

The quality control approaches described in the previous sections are all directed towards detecting any amount of true shift in the measurement process. However, as the imprecision of analytical devices continues to decrease through technological innovation, the use of such methods can become problematic. The evaluation of the quality control approaches previously presented evaluated the ARLs as functions of shifts in the mean in terms of process SD. This is an accepted method of evaluating the statistical performance of quality control approaches. However, as assay variability is continually decreased, the multiples of SD shifts can take on new relative meanings. For example, consider an assay with a 5% coefficient of variation (CV). A 1.0 SD shift would constitute a 5% shift in the mean of the process. If the CV of that assay is reduced to 2.5%, then a 1.0 SD shift would represent a 2.5% shift in the mean of the process. Eventually, the clinical utility of the assay must be considered in the selection and establishment of quality control procedures.

Towards this end, Westgard et al.'s selection grids[10] involve the use of ΔSE_c (i.e. the critical SE to detect) as a parameter for selecting a method. This signifies the appearance of methods designed to detect some specific change identified to be clinically significant or relevant. In other words, changes less than this amount (ΔSE_c) are considered to be of no consequence in the clinical setting while changes this large or larger can have clinical implications. These implications may involve changing a patient's dosage or initiating a change in treatment.

Attempts to define the requirements of clinical laboratory testing systems go back to Skendzel et al.[28] Skendzel et al. mailed a questionnaire to physicians to determine the total precision required for a variety of diagnostic tests. Results at that time indicated that almost all the tests considered provided adequate precision for physicians' requirements. The work was also useful for establishing medically useful guidelines for analytical precision.

Linnet[29] then used Skendzel et al.'s work to calculate what he called "maximum clinically allowable analytical error". Represented by ΔSE_c, this error represents the largest error that can be tolerated according to the requirements outlined through Skendzel et al.'s survey results. Linnet's approach for calculating ΔSE_c is shown

in Equation (4):

$$\Delta SE_c = \Delta_{med} - 1.65 s_t \quad (4)$$

where Δ_{med} = the median difference of medical importance as reported by the physicians in Skendzel et al.'s work and s_t = total precision including analytical measuring system, sample handling, and patient biological variability. Linnet's paper includes a similar approach for defining a critical change in the spread of the measurement system, ΔRE_c. It is clear that the parameters required to calculate the maximum clinically allowable error are not easy to estimate and can be sources of debate.

Koch et al.[30] described an application that incorporates the use of the maximum clinically allowable error in the design of the quality control system for a specific analytical system. Their application uses a consensus process at the testing site to determine the total allowable error (TE_a). Then, they calculate ΔSE_c and ΔRE_c using Equations (5) and (6):

$$\Delta SE_c = \frac{TE_a - |bias|}{s} - 1.65 \quad (5)$$

$$\Delta RE_c = \frac{TE_a - |bias|}{1.96 s} \quad (6)$$

where TE_a = total allowable error for the testing method, bias = known difference between the laboratory's mean and the true mean of the control material, and s = analytical testing system precision. Control methods (number of control replicates and control rules) can then be selected for the individual tests with the requirement of a 90% probability of detecting ΔSE_c.

Many other methods are available for determining the maximum clinical allowable error, as noted by Fraser et al.[31] and Westgard and Burnett.[32] Also, Petersen and Fraser[33] provide an excellent editorial discussing the issues involved with determining this allowable error. Westgard et al.[34] further developed their approach for defining maximum clinically allowable errors using criteria from CLIA 88. This federal regulation outlines TE_a for many analytical tests. Westgard et al. recommend using the total error indicated from CLIA 88 according to Equation (7):

$$TE_a = bias_{meas} + \Delta SE_c s_{meas} + z \Delta RE_c s_{meas} \quad (7)$$

where $bias_{meas}$ = bias in the measurement system, s_{meas} = total precision of the measurement system, and z = standard normal value that sets the maximum percentage beyond TE_a. Using the TE_a associated with the test being analyzed, the user can calculate ΔSE_c and ΔRE_c and select an appropriate quality control scheme.

Although there does not yet appear to be any general consensus in the literature regarding the best approach for defining changes which are clinically significant, it is clear that quality control approaches in the clinical setting are moving towards some amount of allowable error. As the variability inherent in these diagnostic tests continues to become smaller and smaller, there will be stronger movement in the clinical field away from methods which define acceptability limits solely on assay variation. Traditionally accepted methods (e.g. ±2 SD limits) will be replaced with methods incorporating some allowable error or having a total error specification.

8 ECONOMIC ASPECTS

The traditional emphasis for statistical quality control approaches applied to clinical laboratories has been with respect to the statistical performance of the proposed methods. Although the statistical performance of the methods is of utmost importance, the economic aspects of the selected methods must not be ignored. Often, multiple approaches can result in the same statistical power for detecting changes in the measurement process, but the cost associated with the approaches can be drastically different.

Although the application of economic models in the clinical setting is limited, Westgard et al.[35,36] have done some work in the area. In both studies, the authors used a predictive value model to assign costs to various approaches for monitoring quality control. Basically, their model develops the following four situations:

1. the quality control method detects a true change;
2. the quality control method detects a change when there is no change;
3. the quality control method does not detect a true change;
4. the quality control method does not detect a change when there is no change.

Situations 1 and 4 correspond to a correctly working method whereas situation 2 corresponds to a type I error and situation 3 is a type II error. The authors develop probabilities for being in each of the four situations and the costs associated with these situations, comparing methods based on these costs. They can then use their model to predict "quality" (essentially the defect rate) and "productivity" (the test yield).

Recent work with respect to economic modeling of clinical statistical quality control has focused on developing cost equations related to the natural cycle encountered in clinical quality control.[37] The cycle here refers to the testing process beginning in a SOSC (i.e. on target and stable). After operating in control for a period of time, a shift or special cause of variation affects

Figure 3 Illustration of a complete cycle for the economic model.

the testing process driving the state of the process out of control. Eventually, the quality control monitoring approach signals that a shift has occurred and the testing process is shutdown until the cause of the shift is identified. A complete cycle is shown in Figure 3.

Using this model, the testing process is in one of the following states: operating under control (SOSC), operating out of control (OOC), or shutdown. Costs with being in each of these associated states can be specified, resulting in an overall cost equation. The cost of SOSC is essentially a function of testing volume. It includes costs for labor, testing consumables, equipment depreciation, overheads, etc. It can consider the cost of doing business when things are performing as expected. The cost of OOC includes the basic costs related to SOSC, but there is an additional cost component attached. This additional cost relates to reporting patient results which are actually shifted from their true mean. Failing to detect large shifts can result in governing bodies shutting the laboratory down, so this additional cost is very large for major shifts in the measurement process. Finally, there is a cost associated with not generating results when they are needed. This cost reflects responsiveness of the laboratory and may be extremely high for situations when a physician needs rapid turnaround of patient results, but the laboratory is down or not operating. This cost will include basic overhead costs, additional costs for having idle resources on hand, and may include overtime operations for making up lost throughput.

The economic models allows for the incorporation of clinically significant errors. Various magnitudes of process shifts are used as inputs to the model, and the cost associated with these specified shifts can be used to reflect the clinical relevance of the shifts.

9 CONCLUSION

It is clear that a variety of challenges remain with respect to statistical quality control in the clinical laboratory. While traditional methods have been instrumental in ensuring high-quality patient results historically, new needs and requirements for clinical quality control must be addressed. The ever-increasing capabilities of computer technology with respect to summarizing quality control data offer new opportunities. Methods that had been previously infeasible owing to difficulties in implementation can now capitalize on the computer technology available. Training in the application of the outputs of such computer models will definitely be necessary, but complex methods can be applied in a fashion that is transparent to the end user.

Additionally, the consideration of what truly constitutes a clinically relevant change in the measurement process must be integrated into future statistical quality control approaches for laboratories. As instrumentation and assay technology improve, the inherent imprecision of diagnostic assays will continue to decrease. As a result, changes in system performance which are statistically identifiable, yet not clinically important, will become problematic. While there are recommendations as to the level of variability which is clinically tolerable available (CLIA 88), these recommendations are not exhaustive and a general consensus as to the magnitude of allowable errors has not been achieved.

The economic aspect of statistical quality control monitoring for clinical laboratories must also be addressed in the future. While the clinical performance of the laboratory is the first priority, economic aspects of selected methods must not be ignored.

All of these issues constitute future challenges facing statistical quality control in clinical laboratories. Through continued research and transfer of results into the clinical laboratories, the quality of reported patient results will continue to improve in the future.

ABBREVIATIONS AND ACRONYMS

ARL	Average Run Length
CAP	College of American Pathologists
CLIA 88	Clinical Laboratory Improvement Amendments of 1988
CV	Coefficient of Variation
EWMA	Exponentially Weighted Moving Average
OOC	Operating Out of Control
RE	Random Error
SD	Standard Deviation
SD/RT	Standard Deviation Limits with a Retest
SE	Systematic Error
SOSC	State of Statistical Control
TE_a	Total Allowable Error
WR	Westgard Multirule Procedure

Supercritical fluid chromatography (SFC) employs a gas taken above its critical temperature and critical pressure to where it forms a supercritical fluid (SF). SFs have properties of both gases and liquids. They have lower densities and viscosities and higher diffusion coefficients than liquids, but they also have the solvating power of a liquid and can dissolve nonpolar and many polar compounds. As such, these favorable properties combine to make SFs an excellent mobile phase for column chromatography. The SFC technique is highly versatile in that it can be used with either packed columns (similar to high-performance liquid chromatography (HPLC) columns with the same variety of stationary phases available) or open-tubular columns (similar to gas chromatography (GC) columns and employing the same types of coatings) which can be interfaced with a very wide array of detectors. In addition, SFC avoids high temperatures during the chromatographic separation and in most cases the need to derivatize analyzed compounds. These features make SFC particularly well suited to the separation and assay of clinically important biomolecules. As SFC instruments have become commercially available, numerous applications have been explored in the areas of drug monitoring, toxicology, environmental contaminants, and the measurement of physiological biomolecules. Despite its potential, SFC enjoys limited use in clinical chemistry laboratories currently. Greater efforts are needed to improve sensitivity, standardize and validate assays, and work toward high-volume throughput capabilities.

1 INTRODUCTION

The principles underlying SFs have been understood for decades. In 1822 de la Tour[1] reported the disappearance of the meniscus between gas and liquid in a closed system at its critical temperature and in 1879 Hannay and Hogarth[2] demonstrated that salts could be dissolved in condensed gases. However, the use of SFs as the mobile phase of chromatographic separations is much more recent.[3] Moreover, SFC instruments and SFC columns have only been commercially available since about the mid-1980s. This highly versatile technique frequently provides separation efficiencies approaching those of GC, and eliminates the need to work at high temperatures and to derivatize analytes. Hence, it is especially well suited for chemically reactive, heat-sensitive, nonvolatile or higher-molecular-weight compounds. Despite these advantages SFC is still rarely used in the clinical laboratory. Partly this may be related to the existence of well-established and adequate methods for many routinely assayed compounds, to a lack of SFC method development that is specific to clinical applications, to the reality that most SFC instruments are designed for the research laboratory and do not accommodate high-volume throughput, and finally to the limited experience of most clinical chemists with this technology.

2 FUNDAMENTAL CHARACTERISTICS OF SUPERCRITICAL FLUID CHROMATOGRAPHY

A substance becomes a SF when its temperature and pressure exceed their critical points. In this condition, the substance has physical properties that are intermediate between its gaseous and liquid states. For example, SFs have lower densities, lower viscosities, and higher diffusion coefficients than liquids, while still maintaining many of the favorable solvating properties of liquids

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

not present in gases. SFs persist without undergoing the gas-to-liquid transition, despite increases in the external pressure applied to them.

Because of these unique properties, SFs have found many useful applications as mobile phases for column chromatographic separations. The theoretical considerations and background of SFC have been considered in a number of publications.[4–7] As mentioned above, SFC offers the combination of advantages normally associated with GC or LC (liquid chromatography) alone. Because of higher diffusion coefficients, SFs allow for greater radial mass transfer than in the liquid state and, consequently, more efficient separations are achieved than in LC. This affords a shorter analysis time and/or the ability to resolve complex mixtures of analytes. Because of the solvation characteristics of SFs, compounds for analysis need not be volatile as required in GC, but need only be soluble in the SF to allow the technique to be applied.

3 ANALYTICAL CONSIDERATIONS

3.1 Instrumentation

Currently, there are still only a few commercial suppliers of SFC systems.[8] As of this writing, the major vendors of SFC systems are:

- Berger Instruments, Inc., Delaware, Maryland, USA, Tel. 1-(302)266-8201. Their systems are modular and support packed column applications. Components include an autosampler, pumps with pressure regulators, an oven, and an ultraviolet/visible (UV/VIS) absorption detector. Their systems can be interfaced with other instrumentation, including flame ionization detection (FID), nitrogen–phosphorus thermionic ionization detection (NPD), electron capture detection (ECD) and mass spectrometry (MS). Complete systems range in price from about US$45 000 to US$75 000.
- Gilson, Inc., Middleton, Wisconsin, USA, Tel. 1-(608)836-1551, www.gilson.com. Gilson provides complete systems that employ packed column technologies and are based on LC instrumentation. The Gilson system has an external computer unit that operates the pumps and allows for programmable gradient elution capabilities. The detector included with the standard system is a UV absorption detector fitted with a special flow cell. Although other detectors are not provided, different detectors including FID and MS can be used. The cost of a complete system is about US$50 000 currently. They also market packed SFC columns.
- JASCO, Easton, Maryland, USA, Tel. 1-(800)33-5272, www.jascoinc.com; Dunmow, Essex, UK, Tel. (1371)876988, www.jasco.co.jp; Hachioji City, Tokyo, Japan, Tel. (426)66-0682. They provide customized systems and market all of the relevant components. Their systems support packed column SFC applications. The components include extraction cells, pumps, back pressure regulators, ovens, cooling jackets, and a variety of detectors, including fluorescence, diode array, UV absorption, circular dichroism and refractive index. Their systems can also perform HPLC. The list price for a complete system begins at about US$40 000.
- Selerity Technologies, Salt Lake City, Utah, USA, Tel. 1-(801)936-0564. This company produces complete SFC systems that can employ either open tubular or packed microbore SFC columns. Injection is accomplished by means of a computer-controlled valving system; the system has programmable pressure gradient capability. The standard system comes equipped with FID, but can be interfaced with ECD, UV absorption, NPD, or MS. The current retail price is about US$36 000. Both packed and open tubular columns are available.

3.2 Sample Selection

SFs that are compatible with commercial SFC systems, i.e. that are not corrosive or requiring excessive pressures or temperatures, are most easily used for the analysis of nonpolar or weakly polar compounds. Most polar compounds can also be separated on SFC by modifying the mobile phase, which is described hereafter, or after analyte derivatization. Analytes can range in molecular weight from very small molecules up to polymers having molecular weights in excess of 10 000.[9] Many compounds that cannot be separated by GC because of their low volatility, reactivity, or chemical instability are handled with ease by SFC. Hence, many biological analytes are amenable to SFC separation. The technique has recently been applied to the resolution of chiral compounds with excellent success,[10] and this has led to its having extensive application in the manufacture and quality control of drug production. Like most chromatographic separations used in clinical laboratory analysis, appropriate internal standards are required. As with other chromatographic separations, the analyte of interest must typically be extracted from its biological matrix before it can be introduced into an SFC system.

3.3 Sample Introduction

Sample introduction on commercial systems is usually accomplished by means of a high-pressure valving

system. Consequently, the materials to be analyzed are most often dissolved in a small volume of an organic solvent. The sample port typically comprises a loop or an extraction cell in which the sample is introduced. For open tubular columns, loop volumes are of the order of 0.2–1.0 μL of which 10–100 nL are moved onto the analytical column by a time-plotted technique and carried through the analytical column to the detector. Other commercial injection systems support packed column SFC and typically accommodate larger injection volumes of up to a few microliters. Several approaches have been developed to increase the sample volume or, more specifically, to increase the amount of analyte introduced to improve sensitivity. These techniques include solvent venting,[11] which has allowed in some cases sample volumes of 100 μL or more to be introduced, pressure focusing with solvent venting,[11,12] solid-phase extraction,[13–15] or use of a retention gap.[16] This last method, unlike some of the former ones mentioned, is a modification that can be readily applied to commercial systems. Other simple approaches have been employed that involved the use of a reversed-phase HPLC guard column (or precolumn) for off-line solid-phase extraction (our unpublished results). In this approach the analyte in aqueous solution was passed through an octadecylsilanol column and the analyte was retained. Thereafter all of the aqueous solvent was flushed out of the guard column prior to it being placed in series with the SFC column. The analyte (which in this case was a steroid) was eluted from the guard column efficiently by SF carbon dioxide and delivered to an open tubular SFC column for chromatography and detection. Any of these modifications not yet commercially available require additional time for development and validation and a measure of expertise in working with instrumentation. In many cases commercial instruments are not easily adapted.

3.4 Columns

One of the favorable features of SFC systems is that they can employ a wide variety of columns and stationary phases. These include both ''packed'' and ''open tubular'' column types. Packed columns (typically 1–5 mm in diameter) contain spherical silica particles (3–5 μm) to which various organic phases have been covalently bound through the silanol groups of the solid support. The chemical nature of the organic phase provides the separation characteristics. These columns are analogous to HPLC columns and most commercial SFC systems accommodate the use of standard, unmodified HPLC columns. Open tubular columns are typically microcapillary columns made of fused silica which have been coated with nonpolar materials that possess some polarizable capability. The stationary phases are commonly the same materials used to coat GC columns. Typically the stationary phase is covalently bonded to the capillary surface and cross-linked to prevent the solid phase from bleeding from the column. These columns are very similar in nature to GC columns except they have a smaller inner diameter. This is required, both on a theoretical basis and in practice, to achieve the desired column efficiency.[17,18] The theoretical considerations for column selection have been reviewed in greater detail elsewhere.[19,20] Briefly, commercially available, packed columns are short (5–30 cm in length) and have a wider inner diameter (ID) of 1.0–5.0 mm compared to open-tubular columns which are longer with smaller IDs (1.0–30.0 m in length, 25–100 μm ID). Packed columns typically have fewer theoretical plates per meter, although more than 200 000 theoretical plates have been achieved by placing packed columns in series.[21] Even with the use of a single conventional 25 cm packed column, efficiencies of over 20 000 plates are common and would be comparable to a 10 m open tubular column when it used at 20 times its optimal velocity, which is a frequent practice. Recent work on columns has primarily focused on the stationary phase of packed columns. Many new packings have emerged, including those that allow for chiral separations.[9,10] Despite these new packings, there are still concerns about pressure drops over the length of the packed column, which can greatly compromise a column's efficiency, a reminder that longer may not always be better.[9] Despite these concerns, careful determination of the solid phase, temperature, modifier, modifier gradient and other additives can achieve excellent selectivity irrespective of the number of theoretical plates. Packed columns also have higher sample capacities and are well suited for relatively simple mixtures, preparative work, or very dilute analytes. Use of packed column SFC may limit the detection method or at least require specialized approaches to remove or reduce organic modifiers for certain detection modalities. Because of the high mobile-phase flow rates (1–20 mL min^{-1}) used with packed column SFC, it is not possible to use flame-based detectors such as FID. However, most other detection methods are compatible with packed column SFC including MS which is routinely done with packed columns at flow rates of 1 mL min^{-1} or greater without splitting the eluate.

Open tubular columns typically have more theoretical plates per meter and are often better suited for the resolution of complex mixtures. In general these separations are slower, and smaller amounts of specimen can be loaded. As noted, open tubular columns are typically coated with the same types of materials used in GC columns. Most frequently, these are polysiloxanes which

are cross-linked to provide column stability. Some of the side-chain constituents of these polymers include alkyl, aromatic, cyanopropyl, and ethylene oxide groups, again allowing for selective separations. Open tubular column SFC applications typically omit the organic modifier and have much lower flow rates ($1-10\,\mu L\,min^{-1}$) which allow them to be interfaced with all types of detectors, including flame-based detectors.

3.5 Mobile Phase

There are only a few gases that have physicochemical properties that allow them to form SFs under conditions that are compatible with the physical limitations (e.g. heat tolerance, pressure tolerance) of commercial instruments. These gases all have relatively low critical temperatures and relatively low critical pressures, and are also noncorrosive as SFs. However, in a clinical laboratory there are added constraints, including toxicity, flammability, and cost, and hence only supercritical carbon dioxide is used. As a SF, carbon dioxide has a somewhat intermediate solubility parameter. Consequently, there are a number of compounds of analytical interest that are not directly soluble in SF carbon dioxide because of their high polarities. In most cases these analytes can be made soluble by the addition of small percentage of a polar solvent, termed a modifier, to the SF carbon dioxide. Among these methanol is the most common, but others include ethanol, acetonitrile, formic acid, and water.[6,7] The addition of methanol or another modifier changes the solvating properties of the SF carbon dioxide as well as increasing its critical temperature and pressure. These latter changes tend to limit the amount of modifiers that can be added to the SF carbon dioxide. Typically, concentrations of less than 20% organic solvent are used. It should be noted that a specific modifier may have differential effects on solubility, depending on whether the application employs an open tubular or a packed column.[7] Such phenomena as ion pairing[22] or even reverse micelle formation can occur in the presence of certain modifiers.[23,24] Employing organic modifiers typically prevents the use of flame-based detectors and can complicate the use of other detectors such as MS. More recently small amounts of a third mobile phase component, termed an additive, may also be added to optimize separations.[9]

3.6 Elution

As mentioned earlier, SFs have properties not attendant when they exist as gases. For example, the ability to solvate molecules is greater in SFs than in the gaseous state. Moreover, the solvating capacity of an SF increases with its density (and its density is increased with increases in pressure and/or decreases in temperature). Consequently, the ability of the mobile phase to solvate the analyte of interest and displace it from the stationary phase is increased as its density increases. The effect is conceptually like the elution of a compound from a normal-phase HPLC column as the aqueous composition (i.e. polarity) of the mobile phase is increased. Elution in open tubular SFC is most frequently accomplished by increasing the density in a gradient fashion in a programmed manner, typically by increasing pressure. The relationship between pressure and density can be nearly linear for certain regions of the phase diagram. A more detailed treatment of these considerations is provided by Lee and Markides.[6] Even so, the density is not simply a function of pressure, even when temperature is fixed. Temperature programming has been used with some experimental systems to increase both separation efficiency and solvating power.[25] Nevertheless, pressure is much more easily measured and regulated, and it is the means by which all current commercial open tubular SFC systems provide gradient capability.

For packed column SFC the density is usually maintained constant and the portion of organic modifier is increased to accomplish elution of the analyte(s) in a manner that is completely analogous to gradient elution from a reversed-phase HPLC column.

3.7 Detection

Because of the high flow rate or the presence of organic modifiers associated with packed column SFC, flame-based detection does not work well. Of the flame-based methods, the most common is still FID, but other methods include flame photometric and thermionic ionization detection, but all of these have very limited application for clinical targets. Many other types of detectors exist, and in some cases the presence of organic modifiers with packed or open tubular column SFC may limit use of some of these detectors or may require splitting the eluate or require the substantial elimination of solvent prior to detection. Significant progress has occurred in interfacing detectors of many types to SFC, including many commercially available detection systems: spectrofluorimetric; UV absorption detectors, including diode array; Fourier transform infrared (FTIR) spectroscopy, evaporative light-scattering detection (ELSD); refractive index detectors; circular dichroism; and MS, especially MS instruments that have atmospheric pressure ionization capabilities. Open tubular SFC requires that there be a flow restrictor at the end of the column to maintain the supercritical conditions through the column prior to detection. Packed columns need no frit to maintain the pressure but have downstream pressure regulators. To interface packed column SFC with MS, the detector is

positioned after the pressure regulator so as to preserve the pressure control.

In addition, there are several other detector types that have been more recently interfaced to SFC. Although these are still research approaches, they demonstrate the rapid advances being made in SFC, expanding its capabilities. Undoubtedly interfaces for many of these detectors will soon be available commercially. These detectors include the following: proton NMR (nuclear magnetic resonance),[26,27] which was limited to unmodified SF carbon dioxide; chemiluminescent nitrogen detection, which tolerates modifier well and was made sensitive to 25 pg of nitrogen in a drug;[28] sulfur chemiluminescence, which was sensitive to 3 pg of S;[29] electrochemical detection, both amperometric which was sensitive to 20 pg[30] and voltametric which was sensitive to low-nanogram levels of compounds, did not require the introduction of salts, and could be applied to SF carbon dioxide with as little as 1% methanol or acetonitrile;[31] and inductively coupled plasma MS,[32] which allowed for detection of toxic elements in ultratrace quantities.

In terms of the measurement of clinically important or interesting molecules there are some specialized detection needs. For an assay to be useful, the detector must be both specific and quantitatively accurate at physiological concentrations. In the setting of clinical chemistry, one is constantly dealing with very complicated matrices such as serum, plasma, and urine which contain many, chemically diverse analytes. With these considerations in mind some SFC approaches are more attractive than others. The issue of specificity would be anticipated to be very challenging for any detector, but currently the most specific and most universal detection method is MS. In terms of sensitivity, MS, fluorescence, nitrogen and sulfur chemiluminescence and electrochemical detection are quite sensitive and compatible with the physiological concentrations of many clinical chemical targets. Although no one detection method is completely comprehensive, SFC/MS is very promising and has generated substantial interest and attention.[33]

4 APPLICATIONS IN CLINICAL CHEMISTRY

4.1 Fundamental Advantages

4.1.1 Analyte Integrity

Many biological molecules are air or heat sensitive. Certain physiological compounds are susceptible to chemical modification by means of reactions promoted by an aqueous environment, especially once out of the body's reductive environment. Consequently, attempts to use instrumental techniques to separate these compounds with subsequent quantitation has been problematic. In many instances these challenges can be overcome when SFC is employed. Specimens can be introduced onto SFC systems in nonprotic solvents (e.g. methylene chloride, ethyl acetate, dimethyl sulfoxide (DMSO), or acetone), maintained in an oxygen-free environment and handled at temperatures close to the body's physiological temperature. Moreover, SFC is a very clean method, in particular when SF carbon dioxide is used alone. SF carbon dioxide can be obtained in very high purity and any trace impurities present are predominantly other gases, which are quickly lost with depressurization. Even the trace impurities found in organic HPLC solvents can on occasion complicate the analysis of biological analytes present in very minute amounts. Additionally, both packed column and open tubular SFC rarely require the derivatization of analytes, which is commonly required for GC, leaving the analyte intact.

4.1.2 Speed of Use

Because SFC possesses high resolving power and high efficiency, analytes can be resolved rapidly, frequently in under 5 min, when packed columns are used. Times required for capillary open tubular columns often compare favorably with HPLC separation times.

4.1.3 Chromatographic Efficiency

Chromatographic efficiencies that approach those of GC can be achieved by SFC without having to modify the analyte chemically or carry out the separation at high temperature. This of course depends on the analyte and the column used. Open tubular SFC columns can produce over 3000 theoretical plates per meter. For a 30 m column, efficiencies can exceed 100 000 theoretical plates when optimal flow rates are used. In comparison, the use of a 25 cm HPLC column would provide about 20 000 theoretical plates. Efficiencies for packed SFC columns are comparable to the same columns used in HPLC, but packed columns also offer several ways to optimize separations (packing, modifier, additives, gradients, temperatures) and excellent separations can be achieved with the appropriate conditions.

4.1.4 Flexibility

One of the theoretical advantages of instrumental approaches to analyte measurement compared with individualized immunoassays or colorimetric assays is that several molecular species can be measured simultaneously. In principle, even species that are quite different

chemically may be part of the same assay. For this to be successful requires highly efficient separations and highly selective (and quite sensitive) detection, such as MS.

4.2 Limitations

4.2.1 Analyte Solubility

Many clinically important molecules are highly polar or ionic. Such compounds have very limited solubilities in SF carbon dioxide. As mentioned above, modifiers, such as methanol, afford an increased range of solubility for SFC; however, there are likely to be several analytes that are not compatible with this technique.

4.2.2 Clinical Chemical Assays

Clinical chemistry methods are somewhat unique in that there are additional demands placed on these assays that go beyond the traditional requirements of accuracy and reproducibility. Some of these revolve around the issue of sensitivity. In many cases biomolecules of clinical importance exist in picogram per milliliter concentrations or even below. In such cases the limitations of injection volume prohibit the application of SFC currently. In reviewing the current literature, it is also clear that very few SFC applications directly measure endogenous quantities of analytes in plasma and urine. In other words there are few standardized methods for clinical targets in actual biological specimens. Most assays measure standards, occasionally standards in a biological matrix, but very few have measured enough clinical material to validate an assay for potential clinical use. Finally, the clinical chemistry laboratory is expected to provide timely results. Although most SFC applications are in fact rapid, SFC systems are not typically set up for high-volume throughput. All of these limitations are not inherent in the technology per se, but reflect the limited amount of research and development that has targeted the unique needs of a modern clinical chemistry laboratory.

4.2.3 Cost

The cost of an SFC system is comparable to or slightly greater than that of a gradient-capable HPLC system. In addition to the initial cost of an instrument there are the incidental costs of mobile phases and columns. These compare favorably with HPLC or GC. Detectors are no more expensive for SFC than for other column technologies, but they can be expensive. Many clinical laboratories make very limited use of chromatographic techniques such as GC or HPLC and may have a reluctance to use them or SFC because of a lack of experience and expertise. Consequently, with few applications reported in the literature and no commercial method kits available, a laboratory would need to invest substantial time in the development of useful SFC applications. Any instrumental technique requiring significant method development and evaluation may exceed a hospital laboratory's limited resources. Commercial clinical reference laboratories, pharmaceutical industry laboratories, or SFC instrument vendors are much better positioned to take on the time and expense for such assay development.

4.3 Use for Extraction

Supercritical fluid extraction (SFE) has become widely used in the chemical industry to perform analyte extractions from solid matrices. The value of this technology is the ability to perform such extractions without creating organic waste. However, this technique has had very limited use in biomedical applications. The SFE technique has been combined with HPLC to extract and separate compounds of interest from plant materials,[34] coupled with GC to extract and separate flavors or fragrances from plant materials,[35] or coupled with SFC in the analysis of caffeine in coffee beans.[36] A more recent study by Ramsey et al.[37] used SFE to extract drugs from porcine kidney followed by SFC separation and tandem mass spectrometry (MS/MS). This approach took advantage of the drugs being relatively polar compared to other components in the kidneys. To accomplish the extraction, the kidneys were homogenized and lyophilized and a defined amount of the powdered tissue placed in an empty HPLC guard column or precolumn. Neat SF carbon dioxide was then passed through the material and onto an SFC column. The polar drugs were nonetheless solubilized in the mobile phase but were retained by the SFC column which was an amino-bonded Spherisorb® packed column. The drugs were then eluted from the column by a gradient increase of methanol in the mobile phase.[37]

4.4 Previous Applications

The SFC methods that have been developed as clinical assays are still limited in number and are not routinely employed in clinical chemistry laboratories. The analytes for which assays have been developed have included drugs or their metabolites in human specimens such as urine or plasma, environmental toxins in human specimens or in water, and finally physiological molecules. As mentioned above, these assays have not been used in the chemistry laboratory sufficiently to validate their ability to provide reliable therapeutic drug monitoring or to differentiate patients with a particular disease from a normal, reference population.

4.4.1 Drug Analysis

Many drugs have been separated by SFC. Early applications have been reviewed[38–40] as well as more recent

developments.[40] Drug analysis represents the largest single SFC application in the biomedical area. Frequently, these methods represent or have grown out of the monitoring of manufacturing processes. Table 1 lists some general drug classifications to which SFC has been applied together with selected references. The analyses limited only to standards are indicated, and are not discussed extensively. Those that involve the measurement of a drug or metabolite in serum, plasma or urine are given in more detail to provide specifics for SFC approaches that have had a measure of success in working with biological matrices.

Among the first reports of SFC applied to actual biological specimens is the work of Crowther and Henion.[41] They studied a number of drugs using packed columns, coupled to an HPLC system refurbished to accommodate SFC which used MS for detection. In their report they studied caffeine, codeine, and cocaine as pure standards. They also measured phenylbutazone, an anti-inflammatory drug, and its metabolites in an extract of equine urine. For this analysis they used a packed, amino column (20 cm by 2.1 mm ID, 5 μm amino particles, at 70 °C) and SF carbon dioxide modified with 10% methanol as the mobile phase. Elution of phenylbutazone and its metabolites was accomplished in less than 5 min.

Another early set of experiments was reported by Later et al.[44] using SFC to study several groups of drugs. These included glucocorticoids, including the measurement of prednisolone in equine urine. The urine had been previously extracted and details of specimen processing were not given. This group used an open tubular column (18 m by 50 μm ID) that had been coated with methylpolysiloxane bonded to the silica surface and neat SF carbon dioxide was employed as the mobile phase. The column was kept at 130 °C, and a stepped and ramped density gradient was used. Peaks were monitored by FID. Although relatively slow (40 min), SFC provided excellent resolution of these steroids, even for the epimers betamethasone and dexamethasone which differ only by the orientation of the hydroxyl group at the 16-carbon of the steroid ring system. This same paper reported on the separation of tetrahydrocannabinol and six of its metabolites both as pure standards and in extracts of human urine. This was achieved in under 20 min using a 15 m column (with the same inner diameter and coating) at 120 °C but with a somewhat different gradient. Using standards, they also applied the same column and mobile phase to separate tetracycline and oxytetracycline (both antibiotics) at 100 °C and later erythromycin (another antibiotic) at 40 °C. Atenolol, a beta blocker used in the treatment of hypertension, was also readily isolated using the same SFC column and mobile phase but at a temperature of 120 °C and SF carbon dioxide at a constant 0.4 g mL^{-1} density. Finally, they looked at a series of standard drugs of abuse. These again were done on the same column with the same mobile phase and included cocaine, a central nervous system (CNS) stimulant, phencyclidine (hallucinogen), methaqualone (CNS depressant), methadone (narcotic), phenobarbital (CNS depressant), and propoxyphene (analgesic). Clearly, this paper demonstrated the remarkable versatility of the approach and the wide spectrum of analytes that can frequently be separated with a single column type.

Mefloquine, an antimalarial drug, has been analyzed in an extract of human serum by Mount et al.[62] The analyte is basic and its pH was exploited to extract it first from blood (made basic by a sodium phosphate solution) into methyl *tert*-butyl ether. The mefloquine was next back extracted into an aqueous, dilute acid solution. The pH was then modified to be basic and the mefloquine was re-extracted into the ether, which was removed under a stream of nitrogen, and a small volume of a mixture of organic solvents was used to re-solubilize the analyte. The method employed SF pentane modified with 1% methanol and 0.15% *n*-butylamine, a packed column (20 cm by 0.75 mm ID, 7 μm silica particles) at 210 °C, and ECD. Constant-density elution resulted in baseline separation in about 15 min.

Perkins et al.[48] used packed column (100 mm by 4.6 mm ID, 5 μm amino-bonded Spherisorb®) SFC/MS to separate a series of sulphonamide antibiotics which had been added to a porcine kidney extract. The SF carbon dioxide modified with 15% methanol was maintained at constant density through the column at 75 °C and required less than 5 min for the sulphonamides to be separated. Yang and Griffiths have also developed

methods for the analysis of another related antibiotic, sulfanilimide.[68] This method utilized open-tubular SFC (with biphenyldimethyl silicone as the coating), higher than usual pressures (200–500 atm), and FTIR spectroscopy detection.

However, the issue of sensitivity was not considered extensively in earlier SFC drug studies. Wong[69] compared SFC with capillary electrophoresis and HPLC in the analysis of some drugs. He studied FK-206, an experimental immunosuppressive agent, in whole-blood extracts but was not successful in obtaining a measurement by SFC because of the low concentration of drug in a real sample. Pinkston et al.[64] set out to evaluate the feasibility of using SFC/MS on real biological samples. They used solid-phase (octadecylsilanol) extraction of dog plasma fortified with mebeverine, a smooth muscle relaxant. Samples (1.0 mL) were extracted and the extracted material reconstituted in a small volume of mixed organic solvents (0.025 mL). They used an open tubular column (10 m × 50 μm ID, SB-methyl 100 coating) and achieved excellent extraction efficiencies and reasonable separations using this approach. In this early approach of theirs, for a typical run of the 0.6 ng loaded on the system, only 2.6 pg were actually introduced into the analytical SFC column. However, dramatic advances in specimen introduction have been achieved, including later work by Pinkston himself.[33]

Several newer SFC approaches have achieved acceptable sensitivities. A recent study of the anticancer drug paclitaxel used packed-column SFC (with a diol stationary phase) and UV detection to achieve detection limits in the low-microgram range.[70] Others have worked to increase sensitivity to allow for the measurement of other diagnostic targets. One of these involved solid-phase extraction of serum or plasma followed by packed column SFC with either UV or ECD. This approach was used to study mitomycin C, an antibiotic, and employed a 150 mm by 4.6 mm ID column, packed with 5 μm octadecylsilanol bonded particles.[47] Using SF carbon dioxide as the mobile phase and UV absorption for detection, the method was sensitive to 20 ng of drug in 1.0 mL of plasma. A second paper reported on the use of a 200 mm by 1 mm ID column with 5 μm cyano packing, employing SF carbon dioxide as the mobile phase and ECD for measurement of artemisinin, an antimalarial drug.[65] This group also reported a limit of detection of 20 ng mL^{-1}. Although such serum concentrations are achieved for several drugs, measurement of many clinically important endogenous compounds, such as hormones, which occur at even lower concentrations, presents a greater challenge. However, a recent study by Combs et al. suggests that SFC can, with selected detectors, achieve such sensitivities.[28] They used packed column SFC with SF carbon dioxide, methanol as a modifier, and nitrogen chemiluminescence for detection. With the use of a membrane drier and a microbore column, they were able to reduce the minimum detectable quantity to 125 pg of sulfamethazine, an antimicrobial drug. Sulfur chemiluminescence,[29] electrochemical detection[30,31] and MS detection have provided comparable sensitivities in other applications.[71] Nevertheless, improvements in volume capacity in specimen introduction are probably necessary for several potential analytical targets.

Chiral separation of drugs is a rapidly developing industry. Propanol, a beta blocker and an antihypertensive drug, has been separated from several analogs using a packed SFC column that contains chyrosine-A.[10] This approach provided separations superior to those achievable using LC. Alasandro used a Chiracel OD® packed column to separate enantiomers of an oral oxazolidinone anti-bacterial agent, DuP 105.[72] Resolution of the manufactured racemic mixture was achieved by making use of temperature, pressure, modifier concentration, and modifier type. Chiral coatings have also been developed that allow for open tubular SFC. Shurig et al. used Chirasil-DEX® as a stationary phase in a standard open tubular SFC column.[73] Using this approach they were able to separate hexobarbital, a member of the barbituate family.

The use of SFC in the pharmaceutical industry continues to expand. It is no longer a novelty method but is a routine part of many protocols in the monitoring of drug production. Its applicability to so many chemically divergent analytes and its increased ease of operation have made it a valuable analytical tool.

4.4.2 Environmental Toxin Analysis

SFC has also been used in the detection of environmental toxins in human materials. There have been limited studies of this type, but this appears to be a very important application of SFC in the future. Niessen et al.[74] measured the herbicide diuron in plasma. They carried out solid-phase extraction on a SFC precolumn, which retained about 80% of the material loaded. They then used SF carbon dioxide modified with 2% methanol to desorb the analyte from the precolumn. A packed column (150 mm by 4.6 mm ID, 5 μm octadecylsilanol particles) was used for the chromatographic separation, using SF carbon dioxide modified with 2% methanol as the mobile phase, and coupled to UV absorption detection. A detection limit of 30 ng mL^{-1} was reported.

More recently, the urinary metabolites of styrene, used commonly in the production of plastics, were measured in urine by SFC/UV.[75] Organic-phase extraction of urine was used after the urine had been saturated with NaCl. A packed column (150 mm by 3.2 mm ID, 5 μm diol packing) eluted with 1.75 mL min^{-1} SF carbon dioxide modified with methanol–water–methane sulfonic acid, 95 : 5 : 0.01 v/v, was employed and the

analysis was completed in about 12 min. A detection limit was not determined, but samples spiked to 1.5 μg mL^{-1} were readily detected by UV absorption. Another study evaluated 2-thiothiazolidine-4-carboxylic acid (TTCA), which is held to be the best indicator of occupational exposure to carbon disulfide, in urine by SFC.[76] They found that diet accounted for a substantial amount of TTCA after eating uncooked cabbage.

Other work has evaluated environmental contaminants in water by SFC, work that may have implications for clinical chemistry. Phenol and nitrophenols were extracted from both tap and river water and separated by packed column SFC coupled with UV detection.[77] Another approach by the same group used disks with either polystyrene–divinylbenzene or octadecylsilanol as a sorbent to remove polycyclic aromatic hydrocarbons from water. In those experiments the extraction disks could be coupled on-line to the packed column SFC system.[15] They later applied this approach to the detection of low-level organic contaminants in water.[14]

4.4.3 Endogenous Physiologically Important Analytes

The applications of SFC to the analysis of physiological molecules has been limited. The approaches used for these analytes are the same as those used for drugs or environmental toxins. For biomolecules of clinical interest, there are several reports of SFC separations using pure standards, but fewer for the analytes in human specimens such as serum, plasma, or urine. As before, the methods that actually measure biomolecules in biological samples are more extensively reviewed, so as to provide a sense of the range and diversity of approaches that have been used. Other SFC separations of biomolecules that involved only the analysis of pure standards are listed selectively in Table 2 but are not discussed in detail.

David and Novotny[91] analyzed steroids both as standards and as components added to serum or urine. Nitrous oxide was used as the mobile phase (nitrous oxide is extremely dangerous and should not be used). The steroids were quantitatively derivatized to form thiophosphinic esters of their hydroxyl groups prior to SFC. This was done to allow for phosphorus thermionic detection. Sample preparation was consequently involved. Serum or urine was passed over an octadecyl-bonded packing material to extract the analytes and then they were eluted with methanol, dried, and reconstituted in water. Samples were then put through a cation-exchange step (SP-Sephadex), the steroid conjugates being fractionated on a TEAP-LH-20 column (strong cation exchange), and the separated conjugates enzymatically treated to remove the glucuronide or the sulfate groups. Then the various fractions were submitted to anion-exchange chromatography. Thereafter, the steroids were derivatized, which involved a 12 h incubation, and further cleaned up. Finally, the sample was injected onto a 10 m by 50 μm ID column coated with polymethylhydrosiloxane and overlaid with SE-33 (a wax) which was cross-linked. A pressure gradient of 8 atm min^{-1} over 40–50 min was used to accomplish the separation. The detection limit was not determined. Although this approach was successful in providing excellent separations, it is obviously not practical for routine use in the clinical chemistry laboratory where timely results are critical. Edlund and Henion[90] also measured steroids in equine urine. The specimen was collected 2 h after a large-bolus intramuscular injection of prednisolone. In this case the steroid was extracted from sodium borate-treated urine with ethyl acetate. Thereafter, the organic layer was streaked onto a thin-layer chromatography (TLC) plate and chromatographed. The appropriate spot was removed, cleaned of particulates, and introduced onto a packed SFC column (240 mm by 2.1 mm ID, 3 μm cyano-Spherisorb® particles) and delivered to MS by means of an SF carbon dioxide mobile phase. No attempt was made to determine the detection limit. Although effective in extracting and cleaning up the specimen, these methods are simply too time intensive for routine use in the clinical chemistry laboratory.

Scalia and Games[78] studied conjugated bile acids in human bile by means of packed column SFC. Bile was homogenized and centrifuged and the supernatant collected, diluted, and passed over a solid phase (octadecylsilanol) cartridge. The conjugated bile acids were eluted in 0.5 mL of methanol. Of this, 10 μL were injected onto the SFC system which employed a packed column (250 mm by 4.6 mm ID, 5 μm octadecylsilanol coated particles), SF carbon dioxide modified with 20% methanol as the mobile phase, and UV absorption detection. Eight different bile acids were identified in a 13 min run. Bile from patients with liver cirrhosis and hepatitis were compared to normal subjects. This is perhaps the only study to date in which there was an attempt made to evaluate the diagnostic power of an SFC assay approach (even though it was qualitative and not quantitative), even though the

number of specimens assayed was quite limited. The use of SFC to separate and assay bile salts has been recently reviewed and compared to other analytical instrumental approaches.[98]

Serum retanoids have been analyzed by Xie et al.[88] This involved the direct injection of rat serum. Serum (5 μL) was injected as five 1 μL aliquots onto a deactivated, open tubular column using solvent venting. The stream of nitrogen used caused the specimen to be deposited on the surface of the precolumn (2 m by 100 μm ID). Then SF carbon dioxide was used to desorb the materials from the precolumn and carry them into the first analytical column (3 m by 50 μm ID, deactivated with polycyanopropylhydrosiloxane and coated with oligoethylene oxide-substituted polysiloxane (glyme)). This provided a powerful clean-up step. The SFC system was a two-dimensional system that allowed for moving the relevant regions of the first analytical SFC column onto a second analytical SFC column (8 m by 50 μm ID, coated with a liquid crystalline polysiloxane). Both columns employed SF carbon dioxide as the mobile phase and FID was used for detection. Using a spiked specimen, 13-*cis*-retinoic acid was separated from the all-*trans* retinoic acid.

An unusual oligosaccharide was isolated from the urine of patients with gangliosidosis and characterized using SFC/MS or SFC followed by NMR.[94] The neutral oligosaccharides were isolated by a complex series of steps including a celite column, followed by a paper chromatography step that lasted from 4 to 12 days. An open tubular column (10 m by 50 μm ID, coated with diphenyl/dimethylpolysiloxane, 1:1 at 120 °C) was used for SFC with SF carbon dioxide gradient as the mobile phase and chemical ionization MS as the detector.

Others have analyzed cholesterol and cholesterol esters in human serum by SFC. Kim et al.[81] extracted serum with methanol–chloroform (2:1, v/v), the organic phase was collected and dried and the specimen was reconstituted in hexane. Capillary SFC was employed using a column (10 m by 50 μm ID) coated with *n*-octyl- and methylpolysiloxane (1:1). The mobile phase used was SF carbon dioxide with a linear pressure gradient applied over 2 h at 65 °C coupled to FID as the detector. The esters were converted to cholesterol. The method successfully accomplished baseline resolution of 10 separate cholesterol compounds. Nomura et al.[80] also measured these same analytes using a packed column. Serum was processed in a very similar manner, employing methanol/chloroform to extract the cholesterols. Specimens were reconstituted in 50 μL of hexane of which 1 μL was injected. The column was 250 mm by 4.6 mm ID, packed with 5 μm octadecylsilanol bonded particles, and the mobile phase was SF carbon dioxide maintained at 45 °C and 200 atm. Detection was by FID with the run requiring about 20 min. Sjörberg and Markides have recently interfaced SFC with atmospheric-pressure chemical-ionization MS and applied it to cholesterol and fatty acids.[99] Laasko and Manninen have also recently interfaced SFC with atmospheric-pressure chemical-ionization MS to measure lipids.[100] Using a nonpolar packed column they achieved excellent separation of both saturated and unsaturated triacylglycerols. This approach may be readily adapted to more physiological specimens.

4.5 Comparisons with Other Methods

As described throughout, SFC has several favorable chromatographic properties that provide it with a versatility and chromatographic efficiency that compare well with and in many cases exceed other instrumental approaches. The cost for SFC systems and their operation are somewhat, though not dramatically, higher than GC or HPLC systems. The variety of detectors that can be interfaced with SFC continues to grow, affording more sensitive and selective assays. However, the limited use of any of the these instruments in the clinical laboratory currently may perpetuate the status quo given the increasing pressures for laboratories to adopt standardized methodologies used widely at many institutions, and a regulatory environment that discourages method development by individual laboratories themselves. Although automated instruments are in high demand in the hospital setting, most of these are systems developed around the concept that each analyte is measured by a single assay involving unique reagents, whether immunological, enzymatic, or colorimetric. That is to say instruments generally used in laboratories do not rely on separation efficiencies and characteristic retention times to provide isolation of an analyte from other matrix components which can be uniquely delivered to a universal detector. Although SFC provides this added selectivity, such approaches are foreign to most clinical laboratorians and will require education to broaden their perspectives. Additionally, the attractiveness of SFC would be greatly enhanced if sample introduction methods improve sufficiently to allow the capture of most of the analyte in a specimen and thereby increase assay sensitivity. Finally, the general lack of SFC method development specifically for clinical chemistry has been a barrier to its broader use.

5 FUTURE DEVELOPMENTS

The future for SFC is bright. Even in clinical chemistry, rapid and sensitive detection instruments now offer increased specificity and sensitivity while managing large numbers of rapidly eluting analytes from complex matrices such as serum or plasma. Some state-of-the-art systems are expensive and may be beyond the

current resources of hospital laboratories. Consequently the financial means to take advantage of the remarkable potential of SFC seems more likely to reside with commercial reference laboratories, pharmaceutical companies, or analytical instrument companies, which may also create new markets for their services or products in this area. The vast number of broadly used, competitively priced, off-the-shelf assays already marketed specifically to clinical laboratories means that SFC will initially need to develop niche markets, such as in toxicology, assessment of environmental contaminant exposure, and/or therapeutic drug monitoring. It is also incumbent on researchers who develop SFC techniques to apply them more rigorously to clinical chemistry targets, using actual specimens and providing sufficient numbers of assayed patient and control materials to validate these promising methods.

ABBREVIATIONS AND ACRONYMS

CNS	Central Nervous System
DMSO	Dimethyl Sulfoxide
ECD	Electron Capture Detection
ELSD	Evaporative Light-scattering Detection
FID	Flame Ionization Detection
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
ID	Inner Diameter
LC	Liquid Chromatography
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NPD	Nitrogen–Phosphorus Thermionic Ionization Detection
SF	Supercritical Fluid
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
TLC	Thin-layer Chromatography
TTCA	2-Thiothiazolidine-4-carboxylic Acid
UV/VIS	Ultraviolet/Visible

Ultraviolet/visible (UV/VIS) absorption spectroscopy has been used in the clinical laboratory for many years. The technique has appeal, as it is almost universal in its application. Although much of the routine work is performed using high-throughput dedicated clinical analysis systems, absorption spectroscopy still has a place in most clinical laboratories.

This article discusses the range of application types for which absorption spectroscopy can be used and some examples of common analyses are given. The article also discusses the merits of various instrument types and discusses some more advanced spectroscopic techniques, such as derivative spectroscopy, to enhance the data measured by the spectrophotometer. Brief reference is also made to the use of reflectance in clinical analysis.

1 INTRODUCTION

Ultraviolet/visible (UV/VIS) absorption spectroscopy has been used in the clinical laboratory for many years. The technique has appeal, as it is almost universal in its application. The reliance on UV/VIS spectrophotometers (and other spectroscopic techniques) has diminished over the years, however, as dedicated multichannel clinical analyzers and readers have appeared on the market. These analyzers offer high sample throughput and clinically validated proprietary chemistries with ready-mixed reagents for greater speed and convenience. These analyzers normally utilize a range of analytical techniques such as ion-selective electrodes, turbidometry and UV/VIS absorption in one integrated instrument. Reagent manufacturers are also trying to simplify the analysis even further so that much simpler instrumentation is required. There is some work on solid-phase chemistry systems in which the completed reaction on the solid surface can be measured on a simple reader which uses a simple light-emitting diode (LED) source and measures light reflectance from the active face.

Spectroscopic analysis, in general, is in a slow decline in the clinical laboratory as the increasing adoption of molecular biological techniques such as the polymerase chain reaction (PCR) and DNA sequencing are now being used to measure (for example) genetic abnormalities rather than the more indirect biochemistry-based approach.

I have spent some length explaining the fundamentals of the technique and about instrument design. This is deliberate – too often people treat UV/VIS spectrophotometers as a simple ''meter'' without understanding their limitations or suitability for a particular analysis. This article should also be useful for understanding spectrophotometric assays on dedicated analyzers.

2 PRINCIPLES OF ANALYSIS AND INSTRUMENT PARAMETERS

2.1 Fundamentals of Ultraviolet/Visible Spectroscopy and the Beer–Lambert Law

UV/VIS spectroscopy is the study of how a sample responds to light. When a beam of light passes through a substance or a solution, some of the light may be absorbed and the remainder transmitted through the sample. The ratio of the intensity of the light entering the sample (I_0) to that exiting the sample (I_t) at a particular wavelength is defined as the transmittance (T). This is often expressed as the percentage transmittance ($\%T$), which is the transmittance multiplied by 100 (Equation 1):

$$\%T = \left(\frac{I_0}{I_t}\right. \times 100 \qquad (1)$$

The absorbance (A) of a sample is the negative logarithm of the transmittance (Equation 2):

$$A = -\log T \qquad (2)$$

The UV/VIS range of the electromagnetic spectrum covers the range 190–700 nm (most instruments are capable of measuring at longer wavelengths than this, depending on their detector type). For clinical analysis this is useful, as water (most assays are in aqueous solution) is almost completely transparent in this region.

Most clinical assays are concerned with quantitation rather than identification (there are more powerful techniques available to perform the latter) as absorption spectra tend to be featureless – they lack the fine structure which is found, for example, in an infrared (IR) spectrum. Some techniques to enhance resolution and qualitative information will be discussed later.

The most important principle in absorption analysis is the Beer–Lambert law. This law states that, for a given ideal solution, there is a linear relationship between concentration and absorbance provided that the path length is kept constant; the absorptivity (ε) is a constant for each molecule for each wavelength (Equation 3):

$$A = \varepsilon cl \qquad (3)$$

where ε = the absorptivity of the substance, c = concentration and l = path length. Provided that ε and l are kept constant for a given set of experiments, a plot of the sample absorbance against the concentration of the absorbing substance should give a straight line. In practice, a calibration curve is prepared by plotting the absorbance of a series of standard samples as a function of their concentration. If the absorbance of an unknown sample is then measured, the concentration of the absorbing component can be assessed from this graph. Another consequence of the Beer–Lambert law is that it is possible to change the path length to affect the absorbance. This can be useful where lower detection limits are required as the path length can be increased (longer path length cuvettes are available) or, where the absorbance is too high to be measured on the instrument, the path length can be reduced. Alternatively, it is possible to reduce the absorbance by diluting the sample, but one has to take care when dealing with biologically active samples, particularly enzyme-based solutions, as this may have a profound effect on the activity.

2.2 Linearity and Deviations from the Beer–Lambert Law

Above, the Beer–Lambert Law has been shown to be a linear relationship between sample concentration and absorbance. If this relationship is tested experimentally by measuring samples of increasing concentration and the results are plotted, the relationship will be seen to break down with increasing absorbance. With general laboratory UV/VIS spectrophotometers of recent design, this will probably be around 3 absorbance units (AU).

What is observed here is not a breakdown in the Beer–Lambert law (although some assumptions about the sample being infinitely dilute are made in the law) but a limitation in the instrument's performance.

The greatest contributor to this nonlinearity is the instrument's stray light. Stray light can be loosely defined as the amount of light present in the instrument at nonanalytical wavelengths or, put another way, the amount of unwanted light present in the system. This unwanted light can come from several sources. First, there may be light from outside entering the optical system. Manufacturers usually go to some lengths to exclude this light and so it ought to be negligible in a well-designed instrument. The main source of stray light comes from the monochromator itself.

Monochromators (in dispersive instruments) are usually diffraction gratings. These gratings, although highly efficient producers of monochromatic radiation, are not entirely efficient. They will also allow small amounts of light to pass through at other discrete wavelengths, in addition to small amounts of white light. We have seen

Table 1 Observed absorbance readings for three different instrument stray light specifications

True absorbance	1% T stray light[a]	0.01% T stray light[b]	0.0001% T stray light[c]
1.0	0.9788	0.9996	1.0000
2.0	1.8239	1.9957	2.0000
3.0	2.2218	2.9586	3.0000
4.0	2.2924	3.6999	3.9957
5.0	2.3009	3.9586	4.9586

[a] Low-cost or old instrument.
[b] High-performance double-beam instrument.
[c] "Top of the range" double-monochromator, double-beam instrument.

earlier that absorbance is a logarithmic scale and so 1 AU corresponds to 10% T, 2 AU corresponds to 1% T, 3 AU to 0.1% T and so on.

If the light throughput is expressed in percentage terms (%T) and a stray light value (from the instrument manufacturer's data) of 0.05% transmittance is quoted, this will represent a third of the total light seen by the detector at 3 AU (i.e. 0.1% T). This will cause an underreporting of the true absorbance. By 4 AU (0.01% T), there will be more stray light than sample signal, rendering the instrument unusable at this value. Table 1 shows the anticipated effect on the observed absorbance for a range of stray light values which may be encountered on various instruments found within the clinical laboratory.

2.2.1 Other Causes of Non-linearity

Occasionally, there are other reasons why there may be unexpected deviations from linearity.

One major cause is sample fluorescence. If a fluorophore is excited at the same wavelength at which one is trying to measure absorption (the chromaphore), the detector will see a combination of absorbed light and the fluorescence emission. This emission will occur at a longer wavelength than the absorption. It should be borne in mind that there is no monochromator (on a dispersive instrument) between the sample and detector, so the emission will be detected. The observed result will be a lower absorbance reading than expected (as the detector is receiving light from two phenomena instead of one).

If sample fluorescence is severe, it can be removed by inserting a cutoff filter between the sample and the detector. This filter should allow light of the absorbance wavelength to pass through but block higher wavelengths.

Sometimes the linearity can be affected by changes in pH. Some chromophores (the functional group in the molecule responsible for the light absorption) will shift wavelength with a change in pH. If the absorption peak is particularly sharp, it may mean that measurement is no longer at the actual peak but at its side. More sophisticated instruments can detect the actual peak for every measurement or measure areas under the absorption curve between two user-defined points.

Another possible reason for nonlinearity is sample scatter. The instrument expects light to travel through the sample in a straight line (unless there is special provision in the instrument design). If the sample is turbid, this light will be scattered and the light will be splayed out in a cone-like fashion. As a result, less light will fall on the detector and a falsely high absorbance reading will be observed. Turbidity is relatively easy to observe as it is not wavelength specific. A scattering sample, therefore, will have a raised baseline. In bad cases, the baseline may be elevated over 1 AU.

2.3 Cuvettes and Solvents

Apart from ensuring that the instrument design is sufficient for the required analysis, the user must also check that the other components of the analytical system – the cuvettes and the solvents – are applicable for the required task. Cuvettes are offered in either optical glass or quartz. Optical glass will transmit light above 320 nm whereas quartz will transmit light well below 190 nm (the usual low-wavelength limit for UV/VIS spectrophotometers).

As an alternative to glass and quartz cuvettes, several manufacturers offer disposable cuvettes. These are made from various plastics including polystyrene and acrylic. These cuvettes offer the main advantage that they do not need cleaning between samples, which is very useful when handling biohazardous samples. The disadvantages are that they have a restricted wavelength range (one should carefully check the manufacturer's stated wavelength specification before using disposable cuvettes) and they have a lower optical performance. In some cases striations across the face of the cuvette might be observed. These are due to the molding process in the cell manufacture. There will also be a molding mark at the bottom of the cuvette (from the extrusion process) and this can make stirring with a small magnetic flea difficult (with instruments which provide a stirring facility). Another disadvantage with disposable cuvettes is that the cell path length (an important consideration for the Beer–Lambert law) will not be as accurate as with glass or quartz cells and this may have quantitative accuracy implications. Figure 1 shows the light transmission charateristics of some common cuvette materials.

As regards solvents, water has the widest range and the lowest cutoff wavelength. Cutoff wavelengths are somewhat arbitrary and there will be variations in the stated values from different literature sources. I have used the definition as being the wavelength

Figure 1 Light transmission characteristics of various cuvette materials.

Table 2 Cutoffs for common solvents

Solvent	Cutoff (transmittance of 10% in a 1-cm cell) (nm)
Water	190
2-Propanol (isopropyl alcohol)	210
Ethanol	210
Methanol	210
Acetonitrile	210
Dichloromethane	235
Toluene	270
Acetone	330
Chloroform	250

at which a 1-cm cuvette filled with pure solvent has a transmittance of 10% (equivalent to 1 AU). The cutoffs for common solvents are given in Table 2. Some buffers [e.g. tris(hydroxymethyl)aminomethane (TRIS)] have organic components and so it should not be assumed that the cutoff is identical with that for water.

2.4 Resolution (Band-pass) and Slit Width

UV/VIS instruments have a specified band-pass. This term relates to the instrument's ability to resolve peaks which are very close together or "shoulders" (small features on the side of a larger peak). The band-pass will either be fixed, usually between 1 and 2 nm, or, in the case of more expensive instruments, variable (either continuously or in finite steps). Photodiode-array instruments have a fixed optical band-pass as there is no physical slit aperture on these instruments (although the software may be able to simulate other slit conditions); the resolution is defined by the light dispersion, the polychromator and the number of elements in the array.

The band-pass will affect the instrument's ability to discriminate between sharp features. Most molecules possess a broad spectrum, so a small band-pass will not change the appearance of the spectrum (apart from increased noise). Some molecules commonly encountered in clinical analysis, such as porphyrins and the various types of hemoglobin (oxy-, met- and carboxy-) give sharp structures and the position of the peak has to be accurately measured or a misdiagnosis may otherwise result.

Figure 2 shows the effect on a sample with fine structure, i.e. benzene vapor in a sealed cuvette. This is a highly artificial situation, as typical samples in the clinical laboratory do not exhibit such sharp features.

Figure 3 shows the effect of variable resolution on a more typical sample with a single broad peak. In this instance there is little or no difference between a high- and low-resolution (band-pass) scan.

Figure 2 Effect of changing the instrument resolution on a sample with sharp peaks (benzene vapor) showing the effect on band shapes and illustrating sharper discrimination using a 0.5-nm slit (b) compared with a 2-nm slit (a).

Figure 3 Effect of using various slit settings on a typical spectrum with broad bands (spectra offset for clarity) showing that the slit setting is largely irrelevant for broad peaks.

2.5 First- and Second-derivative Spectroscopy

UV/VIS spectra are rather featureless at room temperature, which is why the technique is primarily used for quantitative analysis rather than for sample identification purposes. A broad ultraviolet (UV) spectrum is composed of many separate electronic transitions which, at room temperature, become ''blurred'' to give the appearance of a single entity. Spectra only become more defined at very low temperatures and in the gas phase. Neither of these two conditions is applicable in routine clinical analysis.

One major advantage that UV/VIS analysis possesses for biological measurements is that water (which is the main component of all living systems) is virtually transparent across the entire range (there is some very weak activity around 860 nm) and so any technique to improve the qualitative data is welcome.

Derivative spectroscopy is a useful tool to give some improvement. As the name suggests, the technique consists of plotting the rate of change of the absorbance spectrum versus wavelength. This will give a plot (shown in Figure 4 with the original spectrum). At peak maxima and minima (and also points of inflection), the graph is seen to pass through zero on the ordinate. As a result, the technique can be used to identify peak maxima and minima. This is termed a first-derivative spectrum.

First-derivative spectra have their uses but they are difficult to interpret (as the brain often sees the 'peaks' rather than the true information). If we take the second-derivative spectrum (by derivatizing the absorbance spectrum twice), we obtain a plot such as that in Figure 5.

The second-derivative spectrum can be thought of as an inverted spectrum. Sharp peaks will be made even sharper. Broad peaks (and also broad background

Figure 4 Explanation of the first-derivative (D1) spectrum, and its relationship to the absorption spectrum (Abs).

Figure 5 Second-derivative (D2) spectrum showing sharp band discrimination.

features) will become flattened and so the technique can be used both as a peak-enhancement and background-rejection tool. The second-derivative spectrum, like its absorbance counterpart, still contains quantitative information. If two points are consistently used on the spectrum and the difference in their values on the ordinate is taken, this can be plotted against concentration and a linear relationship established.

Derivative spectra represent an alternative presentation of the original data. Information cannot be created and so there is a cost involved. This cost is at the expense of a much poorer signal-to-noise ratio (as the noise is also being derivatized) and so if a requirement for derivative spectroscopy is anticipated, an instrument with a good noise specification is highly desirable. Single-beam instruments should not be considered for serious derivative spectroscopy.

Higher order derivatives also are possible, and usually up to the fourth derivative is offered on current instrumentation, but the increased noise makes their general analytical use questionable.

2.6 Verification of Spectrophotometer Performance

Clinical analysis is concerned with producing an accurate result to enable the clinician to make an accurate diagnosis and to provide the correct treatment. It is important, therefore, that all equipment used to make the diagnosis is well maintained and that the operators have a sufficient skill level to understand the limitations of the instrument and to use the correct operating and sampling procedures.

Instruments should be checked regularly, using a certified reference material (CRM). As a minimum, the user should possess a sample for checking wavelength

accuracy and a set of absorbance filters. Wavelength standards should never be used to check absorbance accuracy and vice versa. Wavelength standards (such as holmium oxide glass filters) have very sharp peaks whereas absorbance standards such as the National Institute of Standards and Technology (NIST) 930D filters are of neutral density.

Additional checks such as for stray light and noise may also be advantageous. Most instrument companies will be able to give advice on instrument performance checks and routine maintenance.

Microplate reader users are more limited in the choice of calibration aids. For filter-based instruments (the majority at the time of writing), there is no way to check wavelength accuracy (other than to scan the filter on a spectrophotometer) and there are few CRMs available for all formats of microplates. If one is using a microplate reader, the manufacturer should be contacted for advice.

3 OVERVIEW OF INSTRUMENT DESIGNS AND THEIR ADVANTAGES AND DISADVANTAGES

3.1 Dispersive and Diode-array Systems

Before going into details of analysis, it is important to discuss the design of a UV/VIS specrophotometer and the implications of the various design types for a particular analysis, and to understand the limiting factors in making that measurement.

UV/VIS instruments are available in two main types, dispersive and photodiode array (usually shortened to diode array). The dispersive design uses a monochromator before the sample to convert the white light produced by the light source into a single pure wavelength of light. This single wavelength is then passed through the sample and detected. The monochromator can be either a fixed-wavelength filter or a variable-wavelength design such as a prism (rare nowadays) or a diffraction grating. On higher specification instruments, there may be two monochromators linked in series to permit higher performance – particularly at high absorbance values (e.g. over 3.0 AU).

3.2 Dispersive Ultraviolet/Visible Spectrophotometers

Dispersive UV/VIS spectrophotometers have four main optical configurations:

- single beam
- double beam (single detector)
- dual beam (dual detector)
- photodiode array.

3.3 Single-beam Spectrophotometers

The single-beam spectrophotometer is the simplest optical configuration. It consists of a light source, monochromator (either a grating or a filter), the sample area and the detector, as shown in Figure 6. In the single-beam design, it is necessary first to zero the instrument (to establish the I_0 value) and then to measure the sample.

Single-beam instruments are used mainly on grounds of cost. They have poorer noise specifications compared with their dual- and double-beam counterparts and are prone to drifting with time. This makes accurate kinetics and applications involving repetitive sampling over time more difficult. The cheaper models often lack the spectral resolution demanded by some clinical applications (e.g. porphyrin analysis).

3.4 Double-beam Spectrophotometers

In the double-beam design as shown in Figure 7, there is still a single detector – usually a photomultiplier (a phototube). The beam is then sent alternately through sample and reference positions using a chopper wheel or vibrating mirror. The electronics in the instrument are also able to synchronize the beam switching with the detector so that it can distinguish whether the detector is measuring the sample or reference beam at any one time.

Even in complete darkness, a photomultiplier will output a signal. This is known as the dark current. As a result, the beam shuttling device will also have some means of temporarily blocking the light from both beams so that this residual signal (the dark current) can be measured and subtracted from each sample and reference measurement.

Figure 6 Single-beam optical configuration.

Figure 7 Double-beam (chopper wheel) optical layout.

Figure 8 Dual-beam spectrophotometer optical layout.

3.5 Dual-beam Spectrophotometers

An alternative to the double-beam design is the dual-beam layout (Figure 8). In this design, the beam is split using a half-silvered mirror (beam splitter) into its sample and reference components. Each beam has its own detector.

This design is only practical with solid-state detectors (which have fairly constant dark current) and gives equivalent results compared with a double-beam system for most analyses. The design removes the need for a mechanical beam shuttling device (and hence improves reliability) and, as solid-state detectors are used, there is no need for a high-tension power supply to provide the high voltages (around 1000 V) which are required to set the photomultiplier gain. The design also produces very good baseline noise characteristics as, again, there is no contribution from the mechanical beam shuttle. If the design has a weakness, it is at very high absorbance (over 3 AU) as the photomultiplier is able to detect lower light levels than solid-state detectors. Routine clinical analyses rarely exceed these absorbance values and, in any case, a single monochromator instrument is limited by its stray light (see later). If samples exceed the upper absorbance limit of a spectrophotometer, they can either be diluted or a shorter path length cell can be used.

3.6 Photodiode-array Spectrophotometers

Photodiode-array spectrophotometers have been available since the early 1980s with the advent of the early designs from Hewlett-Packard (now Agilent) (Figure 9). The design is basically a single-beam instrument but the sample is irradiated with white light (as opposed to monochromatic light in a dispersive instrument). This light, after it has passed through the sample, is then dispersed by a dispersion monochromator (often referred to as a polychromator) on to a special solid-state detector with individual segments, one for each wavelength. The main appeal of these instruments is that the measurement of a spectrum takes only a few seconds. The system has some disadvantages, however. A diode-array spectrophotometer is a single-beam instrument (although a nonanalytical wavelength may be used as a pseudo-reference to overcome nonwavelength-specific drift). It is also less suitable for some single-wavelength measurements as a whole spectrum has to be collected irrespective of whether the data points are required or not. The design is also more prone to errors from sample fluorescence (as the sample irradiation is at all wavelengths and so any fluorophore present will be also excited) and any nonparallel surfaces in the sample (as this will affect the beam dispersion on to the individual elements in the array). Nevertheless, the diode-array system offers a high throughput of scanned data and the ability also to visualize whole spectrum for single-wavelength analyses so that any unexpected results can be investigated further.

Figure 9 Diode-array spectrophotomer optical layout.

3.7 Microplate Reader Spectrophotometers

Over the past 20 years, many clinical analyses have been transferred from the traditional, cuvette-based spectrophotometer to a microwell (normally 96-well) format. The microwell started life in the early 1960s for microbiological culture. Later, it was realized that the format could be applied to bulk analysis using clear microplates and a dedicated reader.

Microplates are manufactured from plastic (usually polystyrene or acrylic, depending on the required wavelength range). They are cheap, disposable and provide a universal format. The plates also have the advantage that they are compatible with liquid handling devices such as plate fillers and washers.

Although 96 wells is the most common format, the requirement for greater speed and throughput has seen the introduction of even higher density formats such as 384 wells per plate.

The dedicated reader is really a spectrophotometer in an applied form. Most plate readers work in the visible region only (as the polystyrene microplates absorb in the UV region) and use optical filters rather than monochromators. More sophisticated readers may also offer multiple reading modes such as fluorescence and bioluminescence in addition to absorbance. Many modern readers can also be used in conjunction with a robotic system.

In terms of performance, there is a compromise compared with using a spectrophotometer, but for many assays this is far outweighed by the reduced costs and greater convenience which this format offers.

3.8 Reflectance-based Analyzers

In recent years, reagent manufacturers have investigated ways of making tests even more simple to perform and less dependent on expensive analytical equipment. An example of this is the portable glucose monitoring systems which diabetics use to check their blood sugar levels.

The color reaction is performed on a solid support which is coated with the required reagents. This support is usually a small stick or strip. After exposure to a blood or urine sample, this support is inserted in the analytical device and the reading displayed. These devices are based on reflectance rather than absorbance (as the supports are opaque it is not possible to pass light through them).

When light falls on a surface it can be reflected in two main ways, as either specular or diffuse reflectance. Specular reflectance (from the Latin word *speculum* for mirror) is the study of mirror-like reflectance. The path of the reflected ray of light is entirely predictable as it should be at the same angle as the angle of light incidence. In diffuse reflectance, the surface has a matt surface which scatters the reflected light in all directions and this scattered reflectance can be collected by a detector. In practice, a sample may exhibit both types of reflectance (e.g. a coating with a glossy surface) and so the geometry of the collection sphere can be adjusted either to include or exclude the specular component. Reflectance is normally expressed as a percentage compared with a standard – normally a white surface such as Teflon®. The relationship between reflectance and concentration is much less clearly defined when compared with absorbance as there are physical factors to consider (e.g. particle size, layer thickness). A fairly accurate quantitative result can be obtained by taking the logarithm of reflectance or by using the Kubelka–Munk equation. Manufacturers of reflectance-based devices need to spend considerable development work in providing an accurate calibration which can be stored inside the instrument to produce the correct results. These results will need to be verified by regulatory bodies such as the US Food and Drug Administration (FDA) before such a device can be marketed.

As many of these devices are designed for use in the home or general practitioner's surgery, they must be manufactured as cheaply as possible. As a result, an LED can be used in place of a light source and monochromator. Detection is by means of a silicon photodiode or other solid-state detector. A diagram of a reflectance-based analyser for the measurement of blood sugar for diabetes monitoring is shown in Figure 10.

Figure 10 Principle of reflectance-based hand-held analyzer for diabetes monitoring.

4 COMMON CLINICAL APPLICATIONS USING ULTRAVIOLET/VISIBLE ABSORPTION SPECTROSCOPY

There are many clinical tests which employ UV and visible spectrophotometry. For readers who want a detailed and exhaustive list, there are many textbooks on the subject.[1] In this section I have highlighted a range of these tests and detailed how they work.

4.1 Enzyme Rate Assays

Enyzmes are biocatalysts, which are extremely efficient in converting their chosen substrates into product. Apart from their efficiency, they are also highly specific and often will not work with a slightly different substrate.

Often it is useful to study the rate of this catalysis by measuring either the rate of depletion of substrate or the formation of products. This may be a matter of simply measuring the absorbance of one of the reaction components directly or by forming an absorbing conjugate with another molecule.

Enzyme kinetics are usually zero order. This means that, after an initial lag phase, there should be a linear relationship between substrate (or product) concentration with time until one of these components becomes limiting. It is therefore useful if the instrument software is able to allow the user to choose where this linear portion is (either prior to or, better, after data collection) and to use this portion to calculate the rate. The enzyme activity is normally expressed in International Units (IU) by applying a simple factor to the measured slope (absorbance/time).

Enzyme rate assays are nearly always performed at a single wavelength (340 and 405 nm are commonly used) and require a temperature-controlled environment. This may take the form of a simple water-jacketed cell holder where water (or other liquid) is passed through the water jacket at a constant temperature (supplied by a thermostated water circulator). Some cell holders use thermoelectric (or Peltier effect) cell holders. These cell

holders have the advantage of much more precise temperature control and the ability to work below ambient temperatures (Peltier cells can cool by reversing the electric current flow). Some Peltier designs, particularly those requiring high or low temperatures, will still require a flow of cold water in order to operate correctly whereas those covering a more restricted range do not.

Most enzyme reactions are fairly slow, taking place for 5 min or more. In order to increase productivity, most UV/VIS instruments offer a cell changer as an accessory. This is a shuttle device, which can hold six or more cuvettes at once. The instrument then cycles through each of the cell positions taking a reading on each cell every 30 s during the course of the reaction.

The collected data can be analyzed either using the instrument's own kinetic software or externally, using either a computer or manual calculation. Some statistical data on the quality of the curve fit are also useful.

An example of a clinical rate assay is the determination of butyrylcholinesterase (BchE). Certain individuals express a mutant form of the BchE gene. This then encodes for a defective form of the enzyme, which lacks the ability to hydrolyze succinylcholine. In some rare cases, the complete BchE gene is missing. A defective or missing gene will not, normally, be of any consequence. If, however, succinylcholine is used during tracheal intubation in the administration of inhalation anesthetics, this will then cause the patient to undergo complete paralysis. The test for this enzyme[2] is commonly performed using a UV/VIS spectrophotometer with a temperature-controlled cell holder (most tests will be performed at 37 °C).

One important class of enzyme-catalyzed reactions involves the oxidation and reduction of pyridine nucleotides [nicotinamide adenine dinucleotide (NAD^+) and nicotinamide adenine dinucleotide (reduced form) (NADH), respectively]. If the reaction is followed at 340 nm, NAD^+ does not absorb whereas NADH shows a strong absorbance. Examples of NAD^+/NADH kinetic reactions include glucose dehydrogenase,[3] aspartate aminotransferase[4] and urea.[5]

Other enzymatic tests often include a colorless compound, which is added to the reaction. This is then enzymatically converted to a colored product (e.g. *p*-nitrophenol). Examples of this type of test include alkaline phosphatase,[6–8] acid phosphatase[4] and amylase.[1] These tests are included in the summary of common clinical tests in Table 3.

4.2 Colorimetric and End-point Assays

It is also possible to perform a reaction to completion and then to calculate the quantity of initial substrate by extrapolation. This type of assay is termed an end-point assay. There are a vast number of such tests and, if an exhaustive list is sought, the reader is directed to a compendium of methods such as *Tietz*.[1] A summary of some common clinical end-point analyses is given in the summary of common clinical tests in Table 3. The methods will prescribe a time after which the reading can be taken. In the case of enzyme-catalyzed reactions, the incubation time will need to be at constant temperature.

Most diagnostics companies provide premixed reagents to perform these tests together with a detailed protocol describing their use. Different protocols may use slightly

Table 3 Some common clinical tests

Analyte	Method	UV wavelength (nm)
Acid phosphatase[4]	Kinetic: PNP	405
Alanine aminotransferase[9]	Kinetic: NAD^+/NADH	340
Alkaline phosphatase[6–8]	Kinetic: PNP	405
α-Amylase[1]	Kinetic: 2-chloro-4-nitrophenylmaltoheptaoside 2-chloro-PNP	405
Aspartate aminotransferase[10]	Kinetic: NAD^+/NADH	340
Bilirubin[11]	Evelyn–Molloy	555
Cholesterol[12]	Kinetic: cholesterol oxidase	500
Creatinine[13]	Jaffe	510
GGT[14]	Kinetic: carboxy substrate	405
Glucose[15]	Kinetic: hexokinase (NAD^+/NADH)	340
LDH[16]	Kinetic: lactate/pyruvate	340
Porphyrins (total)[17]	Acidification using HCl	Absorbance ~ 405 (Soret peak)
Pseudocholinesterase[28]	NAD^+/NADH	340
Triglycerides[18,19]	Kinetic: GPO colorimetric	520
Urea[20]	Kinetic: NAD^+/NADH	340

PNP, *p*-nitrophenyl phosphate; GGT, γ-glutamyl transferase; LDH, lactate dehydrogenase; GPO, glycerol-3-phosphate oxidase.

altered wavelengths for each analyte. As with rate assays, the test may be based on reading the analyte directly or an additional color reaction may be required to develop the test.

4.3 Immunoassays, Enzyme-linked Immunosorbent Assays and Microplate Assays

Immunoassays rely on the very strong affinity between an antibody and its target molecule (antigen). This strong affinity has been used to design a wide range of assays for a variety of targets. These include pathogens (where a chemical associated with the organism or virus will be targeted), tumor markers and drug monitoring (either therapeutic or drugs of abuse). In fact, anything which can elicit an antibody response can be developed into an immunoassay. These assays are ideal where high specificity is required. They are not good at dealing with a range of possible compounds. For example, it is difficult to design an immunoassay to detect all abused drugs, only specific types. If a ''designer'' drug is synthesized with an additional functional group, this may adversely affect the assay.

Immunoassays are competitive assays. The reaction mixture will contain antigens labeled with some kind of tag (this is either a radiolabel, a fluorophore or a site which will bind to a chromophore). When the (unlabeled) sample antigens are introduced, there will be competition between the labeled and unlabeled antigens and this can be calibrated against a binding curve (which will be sigmoidal in nature). Prior to measurement, it will be necessary to separate the free and bound antigens and so a separation step will be required (heterogeneous assay). Much effort has been spent in previous years trying to simplify this process (e.g. using magnetized, latex-covered beads) or using a technique which inherently separates bound from unbound antigens (e.g. fluorescence polarization) to produce a homogeneous assay. For the highest sensitivity immunoassays, either radioactivity or fluorescence (or time-resolved fluorescence) has to be used. In situations where lower sensitivity is acceptable, an absorption-based assay can be employed.

A popular assay type is the enzyme-linked immunosorbent assay (ELISA). In this assay, an antibody (specific to the analyte) is coated on the bottom of the microplate. In some cases, any exposed area on the microplate (i.e. any area where the antibody has not been coated) is blocked using bovine serum albumin (BSA) and the excess antibody is washed away. The blocking agent is to help prevent unbound antigen from adhering directly to the plate, thus affecting the final result.

The analyte and enzyme conjugate [e.g. horseradish peroxidase (HRP)] is added. The analyte will bind to the antibody, which has previously been coated on the microplate. The enzyme conjugate also binds to the analyte. This will be used later in conjunction with a specific dye to produce the color, which will then be measured on the reader.

4.4 Porphyrin Analysis

Porphyria is the name given to a number of related conditions, some genetic, which result from an over production of porphyrins, which are precursors in the production of hemoglobin. Sufferers are prone to bouts of severe abdominal pain, vomiting, severe personality changes and sensitivity to light. Some types of porphyria produce characteristic dark-colored (''port wine'') urine and this is a good first indication that porphyria is present.

One of the main types of porphyria (a generic term for porphyrin-related disease) is variegate porphyria. In this case a mitochondrial enzyme called protoporphyrinogen oxidase is defective (owing to incorrect genetic coding) and as a result excess protoporphyrin (one of the porphyrin types) is produced. The protoporphyrinogen reacts with oxygen to produce protoporphyrin in an uncontrolled reaction. Other porphyria types include acute intermittent porphyria. Accurate diagnosis of the exact type of porphyria is vital as incorrect treatment could have very serious consequences.

Porphyrins[17] have a characteristic UV/VIS absorption peak (Soret peak) in the region 400–410 nm depending on the type of porphyrin present (coproporphyrin has a peak between 402 and 403 nm whereas the uroporphyrin peak lies between 406 and 407 nm).

The urine sample is filtered, diluted with distilled water and acidified with hydrochloric acid. The sample is scanned between 300 and 500 nm and the spectrum peak positions are noted. The measurement is taken by first constructing a baseline at points at either side of the main peak (usually around 380 and 430 nm) and then measuring the height of the peak down to this baseline (Figure 11).

Figure 11 Porphyrin analysis using three wavelengths.

The total porphyrin concentration is given by Equation (4):

$$\text{total porphyrin}(\mu g\, L^{-1}) = 2A(\lambda_{max}) - (A_{380} + A_{430})\varepsilon \quad (4)$$

where A is absorbance, λ_{max} is the wavelength at maximum absorption and ε is the molar absorptivity (a constant) for the analyte; for porphyrins (in a 1-cm cell) $\varepsilon = 4740\,\mu g\, L^{-1}$.

Alternatively, second-derivative spectroscopy has been used[1] (as this reduces background effects and produces sharper peaks). It should be borne in mind that, for a full and correct diagnosis, the type of porphyrin must be accurately identified. This can only be done using a good UV/VIS spectrophotometer offering narrow slits and a skilled user, as interpretation of the corrected spectrum or the second-derivative spectrum may be involved. UV/VIS absorption spectroscopy is generally used for screening and other techniques such as high-performance liquid chromatography (HPLC) or fluorescence spectroscopy (which gives much better selectivity as each porphyrin has a different excitation and emission wavelength) are often used to make the final, confirmatory, diagnosis. These techniques are usually offered by porphyria reference centers.

4.5 Hemoglobin Analysis

Hemoglobin is a protein with a nonprotein core consisting of an iron atom surrounded by heme groups. It has remarkable oxygen transportation properties where it can change its conformation to accept oxygen (oxyhemoglobin). This process can be inhibited by carbon monoxide, which has a 200 times stronger affinity for hemoglobin (carboxyhemoglobin) than oxygen, resulting in severe respiratory problems and death in cases of carbon monoxide poisoning. Hemoglobin possesses an iron atom core in its ferrous (Fe^{2+}) state. If the iron is oxidized to its ferric (Fe^{3+}) state, its oxygen transport capabilities are diminished and the molecule is called methemoglobin (metHb).

Total hemoglobin can be measured by performing a reaction of the total hemoglobin present with potassium cyanide to form a hemoglobin–cyanide complex (Figure 12).

This is the basis of the method of Zijlstra et al.[20] In this method, hemoglobin is reacted with potassium cyanide (taking great care with pipetting and certainly never by mouth!) and sodium (or potassium) hexacyanoferrate(III) to produce a hemoglobin–cyanide complex (Equation 5):

$$\text{hemoglobin} + CN^- + Fe(CN)_6{}^{3-} \longrightarrow \text{hemoglobin–cyanide} \quad (5)$$

Figure 12 Absorption spectrum of hemoglobin–cyanide complex.

This complex has a peak around 546 nm, which can be measured and quantitated.

Franzini et al.[21] have described a method based on second-derivative spectroscopy to measure hemoglobin and its homologs. This method helps to overcome the interference from bilirubin, which is also often present in these analyses.

Shih et al.[22] also used multicomponent analysis in order to quantitate carboxy-, met- and oxyhemoglobin independently from a single scan. This is a statistical approach which compares each data point in a spectrum with a calibration set of known references – either mixtures or single components – and attempts to calculate the relative proportions of each in the unknown spectrum. This approach has its attractions as it is potentially able to measure each component without the need for a separation step. The main drawback is when there is significant spectral overlap or in situations where the concentrations of the various components differ widely. Problems may also occur if there is a strong background matrix which is not constant. More powerful techniques exist, such as principle component regression or partial least-squares fitting. These techniques are a science in themselves (chemometrics) and go beyond this article.

4.6 Protein Assays

Proteins are composed of amino acid building blocks. Protein has some intrinsic absorbance at approximately 280 nm (from the aromatic amino acids – tyrosine and tryptophan) but it is more common to perform a reaction to produce a colored complex which can be assayed in the visible region. The three most common procedures for protein analysis are biuret, Bradford and bicinchoninic acid (BCA) assays.

Table 4 lists the various protein methods. These are all simple colorimetric determinations.

Table 4 Summary of protein assays

Assay method and reference	Principle	Range ($\mu g\,mL^{-1}$)	Interferences
Lowry[23]	As biuret plus determination of aromatic amino acids	5–200	Phenols, aromatic amino acids
Bradford[24]	Dye binding with coomassie brilliant blue	10–200	Detergents
Biuret[25]	Determination of number of peptide bonds	200–5000	Amines, ammonium salts
BCA[26]	Reduction of copper by protein and formation of Cu(I)–BCA complex	200–1200	High concentrations of metals, strong reducing agents, chelating agents
Absorbance at 280 nm[23]	Determination of tyrosine and tryptophan in protein	>50	Nucleic acids, phenols, aromatics
Warburg–Christian[27]	Determination of aromatic amino acids with compensation for nucleic acids	50–3000 purity check	Phenols, aromatics

Figure 13 Absorption spectrum of DNA.

4.7 Molecular Biology

The use of UV/VIS spectroscopy for molecular biology strictly falls outside the scope of clinical analysis. On the other hand, more routine clinical laboratories are using molecular biology techniques (such as the PCR and automated dideoxy sequencing) as these give more direct diagnosis for genetically based disorders.

As a result of these techniques, UV/VIS spectroscopy is useful for assessing the purity of the starting template in either a sequencing or PCR reaction and, as a result, saves time in optimizing the reaction and helps to reduce reagent costs. Pure DNA and RNA absorb at 260 nm (Figure 13). Protein (which is the main source of contamination) absorbs at around 280 nm (this is dependent on the exact amino acid composition as individual amino acids have slightly different absorption maxima). There is a rule of thumb which is now widely adopted in molecular biology laboratories as a quick method for assessing purity. This method measures the absorbance at 260 and 280 nm and the ratio (A_{260}/A_{280}) is calculated. Optionally, a third reference point can be taken at 320 nm (to assess the amount of turbidity and scatter) and this absorbance value can be subtracted from either of the two absorbance values prior to calculating the ratio. If the ratio of the two absorbances is between 1.7 and 2.0, then the DNA preparation is considered to be pure. If it is >2, then there is probably a high RNA content. A lower ratio would indicate a high protein or phenol content (a reagent commonly used in DNA extraction).

One major issue in molecular biology is sample volume. It is not uncommon to have volumes of 10 μL and so special low-volume cells are available. These special cuvettes are made from quartz (as plastic and glass cuvettes generally absorb below 300 nm). Dedicated low-cost instruments are available for the assessment of nucleic acid purity.

ACKNOWLEDGMENTS

I thank Hanswilly Müller at PerkinElmer, Überlingen, Germany, for providing some of the spectra shown here, Jackie Woolf at the Porphyria Reference Centre, Heath Park Hospital, Cardiff, and Ipswich Hospital, UK, for some information and spectra of porphyrins and Chris Royle at the Brompton Hospital, UK, for keeping me up to date with the latest developments in clinical analysis. I also thank Agilent Technologies (formerly Hewlett-Packard Instruments) and Hypoguard for permission to use their diagrams.

The chemical analysis of urine and other body fluids is an integral part of laboratory medicine today. Clinical chemistry measurements are made in laboratories ranging from large medical research/teaching centers to small rural physicians' offices, and with varying degrees of sophistication in all parts of the world. Indeed, the use of chemical tests at home is currently an important part of monitoring chronic conditions such as diabetes, and this aspect of chemical testing is expected to expand.

This article traces the historical methods of urine testing to provide information on health and disease, from crude visual examination in ancient times to modern techniques using sophisticated chemical instrumentation. The information obtained is useful in the diagnosis of disease, in monitoring the course of the treatment of disease, and in helping to maintain wellness in normal populations.

The chemical tests most widely used in urinalysis are described in some detail along with a discussion of the development of commercial tests leading to the evolution of the diagnostics industry. Chemical tests on other bodily fluids are briefly summarized.

1 INTRODUCTION

Urinalysis has helped throughout the ages to diagnose disease. We briefly review the history of its development, from primitive urinalysis consisting mainly of observation of specimens to modern uses of chemical reagents and automated instrumentation. An older but more detailed presentation is found in our book, *Urinalysis in Clinical Laboratory Practice*.[1] With the creation of the diagnostics industry, the application of analytical chemistry to the diagnosis of disease has allowed the clinical laboratory to provide more precise, more accurate, more useful and more rapid information to the physician. Moreover, chemistry allows the patient to monitor chronic conditions such as diabetes directly and thus assume more responsibility for his or her own health. Because the analysis of urine does not require invasive specimen collection procedures, the immediate future appears bright for its continuing utility. It also seems that the kidney's role in excreting a variety of metabolites assures urinalysis a continuing place in analytical chemistry.

2 HISTORY OF URINE TESTING

The practice of using information from urine testing to indicate disease or abnormalities begins in ancient times,

Figure 1 An ancient symbol for urine, as one of the elements of nature.

continues through the present time and is likely to be expanded into the foreseeable future.

2.1 Ancient Times

Before there was written language, symbols were used for important natural elements and shown in Figure 1 is the symbol used for urine.[2] As early as 400 BC Hippocrates noted the different odors and color of urine. About 1000 AD, Ismail of Jurjani recorded seven observations which could be made on urine for various interpretations. These were: quantity, consistency, color, odor, transparency, sediment, and froth.

Visual observations continued, and in the Middle Ages physicians were known as uroscopists and were nearly always painted peering into a container of urine – the urine glass that is seen in many engravings of the 13th to 15th centuries. This was a round-bottomed flask called a matula, and is depicted in Figure 2. Uroscopy later developed a poor reputation because charlatans, or uromancers, used the examination of urine not only to provide information about health and disease, but also as sort of a fortune-telling exercise to foretell the future. Such quacks were known as ''Pisse Prophets''. A review of the role of urinalysis in the history of diagnostics medicine gives many more details of urine study before chemical analysis of urine was used.[3]

2.2 Microscopic Examination of Urine Sediment

Of course, the visual examination of urine continues today with the microscopic examination of urine sediment. Chemical stains are often used to enhance the differentiation of the various elements formed. The addition of acetic acid to the sediment causes red cells to hemolyze and aids in their identification. Knowledge of the urine pH is also useful in the identification of sediment. Chemical tests are often used to identify various crystals in urine.

Figure 2 The painting *The Physician* by Franz Christophe Janneck showing the matula, the urine collection vessel used by physicians of the time. (Reproduced by permission of Fisher Scientific.)

2.3 Chemical Tests

In the 1600s, Scribonius described the black urine in alcaptonuria, Frederick Dekker of Leyden detected protein in urine using heat and acetic acid, Herman Boerhaave measured the specific gravity of urine, and Thomas Willis tasted urine to detect the sweetness of urine caused by diabetes (and it was only a century later in 1776 that Matthew Dobson proved that the sweet taste was due to sugar).

In the 18th century, several chemical tests were developed specifically for use in urine studies. They included yeast fermentation for urine sugar, nitric acid precipitation of protein in urine, and the nitric acid colorimetric bilirubin test made popular by Leopold Gmelin. In 1841, Trommer introduced his test for sugar, which involved the reduction of blue cupric ions in hot alkaline solution; this test was later improved by Herman

von Fehling. Perhaps the most widely known liquid test for urine sugar was described by Stanley Benedict in 1911, when he was a student at the University of Cincinnati.[4] He not only devised Benedict's qualitative solution for the estimation of urine sugar, but also developed a quantitative volumetric method in which the extent of copper reduction in a given volume of Benedict's quantitative solution was carefully determined by titration while the solution was kept boiling over a Bunsen burner. Benedict made many contributions to analytical chemical methods during his career as Professor of Chemistry at Cornell University. Otto Folin of Harvard University Medical School was another famous biochemist who contributed to the early advances in clinical analytical chemistry, and Meites[5] has written his biography. It is our belief that Victor C. Myers, who received his doctorate from Yale University in 1909, created the first real clinical laboratory with the extensive application of chemical measurements to blood and urine at the New York Postgraduate Hospital. This can be considered the beginning of 20th century urinalysis. In 1906, Dr Charles P. Emerson of Johns Hopkins University wrote the textbook *Clinical Diagnosis*,[6] a significant part of which is devoted to urine study. For the first quarter of the 20th century, this text profoundly affected the importance of urine study as viewed by the medical profession.

2.4 Convenient Urine Tests

The idea of providing convenience to the clinical study of urine was first noted by Dr Walter Compton, who with Maurice Treneer (the chief chemist at Miles Laboratories in Elkhart, Indiana), devised a simple tablet containing cupric sulfate, sodium hydroxide, citric acid and a little carbonate.[7] (After all, Miles was the maker of Alka-Seltzer®, which also fizzed!) This test, Clinitest®, is still widely used and when a tablet is dropped into a test tube containing urine, the heat of solution of the sodium hydroxide and the exothermic reaction of sodium hydroxide with citric acid supply enough heat to allow the sugar of the urine to reduce blue cupric ions to orange or red cuprous ions. Color blocks from blue through green to orange represent the amount of color change, and can be used to estimate the sugar concentration of the urine specimen tested. Essentially, this allows the copper reduction test to be performed without an external source of heat.

Our group, the Biochemistry Section of the Miles Ames Research Laboratory, continued to advance the convenience of urine testing by producing other single-use reagent tablets: Acetest® for urine ketones and Ictotest®, the ultrasensitive test for urine bilirubin. Both of these tests are still widely used today even after the introduction of the very convenient ''dipstix'' in 1956.

2.5 Dip-and-read Reagent Strip Tests

At the 1956 International Congress of Clinical Chemistry in New York, the first dip-and-read test was described by our group. This was Clinistix®, a simple specific test for urine glucose. In the same year, Eli Lilly & Co., leaders in supplying insulin to those with diabetes, introduced Tes-Tape® which is based on the same chemical principle. Glucose was, and still is, the most common urine analyte in the clinical laboratory. Urine protein is the second most common test, and the colorimetric test for protein was introduced in 1957. Since these two tests were performed on almost every urine specimen reaching the laboratory, it seemed logical to provide both tests on the same dip-and-read strip, and thus the first multiple reagent dip-and-read test was created, for glucose and protein. The next additions to the multiple reagent strip were tests for pH, occult blood and ketones. In 1969 the liver function tests for bilirubin and urobilinogen were added. In 1972 the nitrite test for urinary tract infections (UTIs) or bacteriuria was added. And in 1981 the colorimetric test for specific gravity finally came into being. In 1984 another indirect test for UTIs, a test for leukocyte esterase, was added as the final test of the ten-way multiple reagent strip. Each of these tests is a colorimetric test, and the reagent is matched to a series of color blocks of increasing intensity, proportional to the amount of analyte being determined. A color chart is shown in Figure 3.

2.6 Automation

In 1972, automation was introduced to the urinalysis laboratory with the large-volume laboratory instrument called Clinilab®. Reagent areas for each test were spaced on reels and fed through the sampler apparatus; the color intensity of the reacted reagent was measured by reflectance spectroscopy. Specific gravity was measured by the falling drop method, in which the time a drop of urine takes to travel between two marks, through a column of viscous fluid, is converted into specific gravity units. The Clinilab® was a ''walk-away'' instrument with automatic printout of results on a data tag attached to the urine specimen tube, so that no recording errors could occur. A semi-automated instrument, a ''strip reader'' called Clinitek®, was introduced for small-volume laboratories and physicians' offices. This required the analyst to dip the reagent strip into the specimen and place the reacted strip on a tray table. Results were displayed on a lighted panel and copied by the analyst. Many improvements have been made over the years, and the latest version of the larger instrument is called the Clinitek® 500, while the smaller instrument is the Clinitek® 50. This latter instrument can also be used with the newest products, Clinitek® hCG, a test

Figure 3 Color chart for the ten-test multiple dip-and-read urine reagent strip. (Reproduced by permission of Bayer Corporation.)

for human chorionic gonadotropin (HCG), and Clinitek® Microalbumin, a test for microalbuminuria. A timeline adapted from a previous publication[8] and noting many of the important milestones in urine testing is shown in Table 1.

3 EVOLUTION OF URINE AND BLOOD TESTING USING DIABETES TESTS AS THE EXAMPLE

In ancient times, urine was poured on the ground to see if it attracted insects. The attraction of insects indicated an abnormality then known as 'honey urine'' which was correlated with what later became known as diabetes. As mentioned in section 2.3, the method of ''taste testing'' was used by Dr Thomas Willis in the 1600s. Metal reduction tests that relied on the fact that glucose is a strong reducing agent to detect and quantitate its level in urine or blood were used in the early 1900s. Copper was the usual reagent but bismuth reduction was also utilized. The development of the convenient copper reduction test in tablet form was the culmination of the reduction tests. The biggest disadvantage of copper reduction tests was the fact that any reducing substance present in the urine specimen would react in the same way as glucose. This led to the use of the enzyme glucose oxidase to produce a test formulation specific for glucose. The same disadvantage of nonspecificity was also

Table 1 Timeline with various milestones in the development of urine testing

Ancient times	Insects – honey urine
400 BC – Hippocrates	Color/odor/fever
1000 AD – Ismail of Jurjani	Seven observations
Middle Ages – Uroscopy	''Pisse Prophets''
1673 – Dekkers	Boiling acetic acid – protein
1674 – Willis	Sweet taste – diabetes
1674 – Boerhaave	Specific gravity – dehydration
1827 – Bright	Heat/acid/protein – renal
1911 – Benedict	Alkaline Cu reduction – sugar
1942 – Compton	Self-heating tablet – Clinitest®
1956 – Free et al.	''Dipstix'' – Clinistix®
1958 – Ames	First multiple – two tests
1972 – Ames/Miles	Automation
1984 – Miles	Ten-test multiple
1990 – Miles	Clinitek® 100
1997 – Bayer	Clinitek® Microalbumin Clinitek® hCG

true of blood glucose measurements, and the enzymatic reaction gradually replaced the reduction methods in the laboratory. The adaption of the convenient dip-and-read methodology for use on whole blood from finger punctures provided a convenient blood glucose analysis usable in any place, and at any time of the day or night. It thus allowed stricter control of blood glucose levels and provided a convenient alternative to trips to the doctor's office or the hospital laboratory. To help standardize the reading of results of the colorimetric test, an easy-to-use reflectance spectrophotometer was devised to read the intensity of color formed in the chemical reaction. The most recent tests utilized in the control of diabetes are the tests for glycated protein and microalbuminuria. Glycated hemoglobin, or Hb A_{1c}, is increased in persons with diabetes whose blood glucose is out of control for several days. It is a good monitor for checking the success of the therapeutic regime the diabetic patient is supposed to follow. The test for microalbuminuria is a predictive test. It has been shown that very small amounts of albumin excreted consistently by the kidney indicate that further deterioration of the kidney is likely to occur. Early detection of microalbuminuria allows steps to be taken to delay the onset of renal failure.

4 MOST COMMON URINE ANALYTES

Throughout this section, the chemical principles described are those commercially available under the series of Multistix® trademarks from Bayer Diagnostics. Similar products may be available under the Chemstrip® trademark from Roche Diagnostics, under the Rapignost® trademark from Behring Hoechst, and from KDK in Japan and others in the Far East.

4.1 Glucose

Glucose appears in the urine of a person whose pancreas does not produce active insulin to allow the body's cells to metabolize glucose. Consequently the glucose level rises in the blood and when it becomes so high that the kidney tubules cannot reabsorb it all, it spills over into the urine. The specific test for glucose is a double sequential enzymatic reaction. The reagent contains glucose oxidase, peroxidase and a potassium iodide chromogen. Glucose oxidase reacts with glucose to form gluconic acid and hydrogen peroxide. In turn the peroxidase of the reagent reacts with the hydrogen peroxide to oxidize the chromogen to a colored compound. The intensity of color is proportional to the glucose concentration.

4.2 Ketones

Ketones are breakdown products of fat metabolism. When individuals cannot utilize carbohydrates to fuel their body cells, the cells use fat for fuel. The most common instance of fat metabolism is in diabetes where insulin is not available. However, in starvation or vomiting with no or little food metabolized, or in high fat diets, ketones may also appear in the urine. The ketones, acetone and acetoacetic acid react in strongly alkaline media with nitroprusside to form a purple color. The intensity of color is proportional to the concentration of ketones.

4.3 Protein

The principal protein appearing in the urine as a result of kidney dysfunction is albumin. This protein leaks from the serum through the damaged glomerular filter into the urine to signify renal disorder. Albumin is determined by using the principle of the protein error of indicators. Some acid–base indicators are subject to protein error; that is, they turn the color that indicates alkalinity in the presence of protein even if the pH is kept constant. In the protein reagent, the indicator tetrabromophenol blue is buffered strongly at an acid pH and is a yellowish color. Thus any blue color formed when the strip is dipped into a urine specimen is due to protein and not to a pH change. A highly buffered alkaline urine may occasionally overcome the strong acid to give a pH color change.

4.4 Occult Blood

Blood appears in the urine as a result of kidney disorder. The glomerular filter damage is great if cells can get into the urine. Red cells will hemolyze in a dilute urine

specimen or when they are damaged during the course of urine flow through the kidney. Hemolysis releases hemoglobin from the cell and it is the peroxidase-like activity of hemoglobin which is detected with this reagent. The reagent contains a solid peroxide and the chromogen 3,3′,5,5′-tetramethylbenzidine. The reaction is similar to the second enzyme reaction of the glucose test. The peroxidase-like hemoglobin catalyzes the reaction of the peroxide to form the oxidized (blue) form of the chromogen.

4.5 Bilirubin

Bilirubin is the normal breakdown product of hemoglobin and it circulates in the bloodstream bound to the plasma albumin. Thus there is normally no bilirubin in the urine since albumin is too large a molecule to filter through the kidney. However, the liver conjugates bilirubin into the glucuronide, a soluble product excreted through the bile into the intestine where the normal intestinal bacteria reduce bilirubin to urobilinogen, which is further reduced to urobilin and excreted in the stool. A small amount of urobilinogen circulates in the bloodstream and appears in the urine. If the liver and biliary system do not function properly, then bilirubin glucuronide backs up into the bloodstream and appears in the urine. The principal causes of bilirubinuria are biliary obstruction and hepatitis. In fact, detection of bilirubin in urine may be an early sign of hepatitis. The test is based on the coupling of bilirubin with diazotized dichloroaniline in the presence of strong acid to give a tan color. Bilirubin is light sensitive and it is essential that the urine be tested as soon as possible after excretion.

4.6 Urobilinogen

As noted in section 4.5, a small amount of urobilinogen is not excreted into the bile but circulates in the bloodstream. Therefore a small amount of urobilinogen is normally present in the urine. Urobilinogen is *absent* from the urine in cases of obstruction of the bile duct and is *increased* in other types of liver damage such as hepatitis, cirrhosis and in blood disorders such as hemolytic anemia where excess hemoglobin passes through the liver. Table 2 shows how testing for bilirubin and urobilinogen in urine can help provide a differential diagnosis of liver disease. The test is based on the Wallace and Diamond reaction; in strong acid, urobilinogen reacts with *p*-diethylaminobenzaldehyde to give a reddish-orange color, the intensity of which is proportional to the amount of urobilinogen present.

Table 2 An indication of how testing the urine for bilirubin and urobilinogen aids in the differential diagnosis of liver dysfunction

Diagnosis	Urobilinogen	Bilirubin
Health	Normal	Negative
Hemolytic disease	Increased	Negative
Hepatic disease	Increased	Positive or negative
Biliary obstruction	Low or absent	Positive

4.7 Nitrite

The test for nitrite in urine is an indirect chemical test for bacteriuria or UTIs. Most bacteria which cause kidney or bladder infections secrete the enzyme reductase which reduces nitrate to nitrite. There is nitrate present in urine because it is an end product of protein metabolism, but nitrite is never normally present in urine. Therefore if the test for nitrite is positive it always indicates the presence of significant numbers of bacteria – generally 10^5 organisms per milliliter of urine. However, a few cases of UTIs are caused by bacteria which do not secrete reductase and therefore will not reduce nitrate to nitrite. Thus the nitrite test does not give a false positive result but in some cases does not react in the presence of bacterial infection. In this test, nitrite reacts with *p*-arsanilic acid to form a diazonium salt, which couples with 1,2,3,4-tetrahydrobenzo(h)-quinolin-3-ol to produce a pink color.

4.8 Leukocyte Esterase

Leukocytes or white blood cells are usually present in urine when there is an infection in the urinary tract because they are the cells which fight to destroy invading bacteria. Leukocytes release the enzyme leukocyte esterase into the urine and thus the test for leukocyte esterase is another indirect test for bacteriuria or UTIs. The chemical test for leukocyte esterase is based on the hydrolysis of the derivatized pyrrole amino acid ester to liberate 3-hydroxy-5-phenyl pyrrole. This pyrrole reacts in turn with a diazonium salt to produce a purple color.

4.9 pH

The normal urine pH ranges from 5 to almost 8. Urine pH varies in relation to the diet and the time of urine collection after eating, with acid urine excreted by individuals on high protein diets and alkaline urine excreted by those on diets high in vegetables and dairy products. Certain medications may cause typically acid or alkaline urines. The urine is likely to be acid in uncontrolled diabetes, and alkaline in UTIs. The reagent for the colorimetric determination of urine pH is a combination of methyl red and bromothymol blue. This gives a broad range of colors from orange at pH 5 through yellow and green to dark blue at pH 8.

4.10 Specific Gravity

The specific gravity (density) of urine varies with the amount of liquid ingested and excreted and is usually inversely related to the volume of urine. It is a measure of the amount of solids dissolved in the urine. Specific gravity values may be close to those of water (1.000) after intake of large amounts of liquid or in diseases such as diabetes or kidney disease. In contrast, in states close to dehydration from high salt ingestion, or excess perspiration, vomiting and diarrhea, the specific gravity may be as high as 1.030 or more. The unique colorimetric specific gravity test is based on the apparent change in pK_a of the polyelectrolyte poly(methyl vinyl ether/maleic anhydride) in relation to ionic concentration. The indicator, bromothymol blue, is a deep blue-green color at low ionic concentration and changes to a yellow-green color at high ionic concentration. Ionic concentration of urine is directly related to specific gravity as determined by physical measurements.

4.11 Clinitek® Microalbumin

This is a reagent strip with two tests, one for creatinine and one for microalbumin. It is a useful test to identify the early stages of kidney damage, which is particularly important for patients with diabetes or hypertension. In order to allow the use of random specimens, the albumin-to-creatinine ratio is provided as milligrams albumin per gram or millimole creatinine. Albumin-to-creatinine ratios of $30–300\,mg\,g^{-1}$ creatinine indicate microalbuminuria. The test is read on the Clinitek® 50 (described in section 2.6). The creatinine reagent is based on the peroxidase-like activity of a copper creatinine complex, which catalyzes the reaction of diisopropyl-benzene dihydroperoxide with 3,3′,5,5′-tetramethylbenzidine. The microalbumin reagent is based on dye binding using the buffered high affinity dye 3′,3″-diido-4′,4″dihydroxy-5′,5″-dinitrophenyl-3,4,5,6-tetrabromo-sulfonephthalein, with the resulting color ranging from orange to blue. Positive results from microalbuminuria testing are an indication of the likelihood of impending renal damage and proper intervention can delay serious kidney problems.

4.12 Human Chorionic Gonadotropin

HCG is the time-honored analyte which indicates pregnancy. The placenta produces this hormone soon after the fertilized egg is implanted in the uterus. The Clinitek® hCG reagent is based on an immunochemical reaction. The reagent strip is dipped into the urine specimen and the urine migrates through an area containing a monoclonal antibody specific for the beta subunit of HCG. Any HCG in the urine is bound to the antibody; the complex continues to migrate and is bound to a polyclonal antibody for the alpha subunit of HCG, which is immobilized on the strip. The instrument then displays or prints ''negative'' or ''positive''; a positive result is obtained with HCG concentrations of $25\,mIU\,mL^{-1}$ or greater.

5 LESS COMMON URINE ANALYTES

There are literally hundreds of analytes in urine which in special circumstances can provide useful information. The fact that urine is an easy-to-obtain noninvasive specimen makes it the specimen of choice in many instances. Two of these groups of tests will be briefly discussed.

5.1 Inborn Errors of Metabolism

Several important analytes for which chemical analysis has been developed are in the excretory products caused by inborn errors of metabolism. Analytes appear in urine as a result of defects of various body systems. Most of them are best tested for on newborns since they may lead to mental retardation or other disabilities, and such consequences can be prevented in some instances if early detection is made. One inborn error was originally detected by testing urine for phenylpyruvic acid as a sign of phenylketonuria (PKU). This compound reacts with ferric ions to give a blue-gray or green-gray color. It is the product of faulty metabolism of the essential amino acid phenylalanine. If PKU is detected during the first several weeks of life, the infant can be placed on special protein hydrolysates with phenylalanine removed thus preventing the mental retardation which occurs in PKU. All infants in the USA are by law tested for PKU at birth, but blood phenylalanine assays are now used. Amino acid chromatography of urine is also used on infants suspected of having other amino acid abnormalities such as maple syrup urine disease, cystinuria or homocystinuria. Galactosemia is an inborn error in which galactose cannot be metabolized by the liver and is excreted in the urine. It is rare but testing is important since removal of lactose from the diet will prevent the mental retardation and early death seen in infants with this metabolic error. The screening test combination for galactose is a positive reducing test and a negative glucose oxidase test, with confirmation of galactose by more specific measurement.

5.2 Drugs of Abuse

Urine is the test substance of choice for detection of substances of abuse. Thin-layer chromatography (TLC) is often used. Several commercial products are available for testing for the metabolites of such drugs as morphine, cocaine, marijuana, amphetamines, and barbiturates.

The most widely used immunochemical test systems are EMIT® from Syva and Abuscreen® from Roche Diagnostics. Roche has recently introduced a rapid test called OnTrack TesTcup® er.

6 OTHER BODILY FLUIDS

Most other bodily fluids used for chemical analysis are obtained by invasive techniques. And the most important, blood or serum, will be covered in other chapters of this encyclopedia. The following brief discussion summarizes bodily fluids other than urine.

6.1 Serum or Blood

There are many blood analytes of importance in health and disease. Presently most analyses are performed on serum rather than whole blood since analytes such as glucose are more stable if the red cells are removed and reagents can be reacted directly with serum while whole blood requires protein removal by precipitation and filtration. All tests are ordered from the clinical chemistry laboratory as single tests by physicians, and several may be grouped into panels pertaining to specific types of disease or particular possible sites of dysfunction, e.g. liver panel, cardiac panel. Tests range from easy-to-perform bedside analyses to those involving sophisticated complicated instrumentation that must be carried out in the main or specialized laboratory.

6.2 Sweat

The usual analyte of importance in sweat is sodium or chloride, as a presumptive test for cystic fibrosis. The most difficult part of the analysis is the collection of the specimen, since testing is usually performed on infants or small children.

6.3 Cerebrospinal Fluid

The important chemical analytes in cerebrospinal fluid (CSF) are total protein and glucose – especially in relation to meningitis, in which total protein is elevated beyond the normal 14–45 mg dL^{-1} while glucose is decreased from the normal level of 50–60% of the serum concentration. The enzymes lactate dehydrogenase and creatine kinase are also occasionally measured in CSF.

6.4 Amniotic Fluid

Specific chemical tests are performed on amniotic fluid in order to detect serious conditions in the fetus. Spectrophotometric readings for bilirubin/bilirubinoids are used to detect hemolytic disease of the newborn. Fetal lung maturity is determined by measurement of the lecithin–sphingomyelin ratio or by TLC determination of phosphatidylglycerol. Alpha fetal protein levels are measured to predict neural tube defects such as spina bifida.

6.5 Tears or Saliva

Tears and saliva have often been suggested as substitutes for serum, mainly to avoid the trauma associated with obtaining blood specimens. Diabetics who often collect fingertip blood specimens several times a day would particularly appreciate substitutes.

6.6 Stools

Although stools are technically not ''other bodily fluids'', these specimens are grouped in this category in most clinical discussions and texts. An important analyte in stools is blood. Blood appears in the stool in the presence of colorectal cancer and is an easy, inexpensive cancer test. Blood can also appear in the stool as a result of bleeding stomach or duodenal ulcers or, in some cases, as a result of more benign causes such as bleeding gums. However, repeat tests after discussion with the patient can often clarify the source. Colorectal cancer detection must always be confirmed with physical tests such as colonoscopy or sigmoidoscopy.

6.7 Miscellaneous Bodily Fluids

A recent textbook[9] describes the analysis of a variety of body fluids other than urine. It include several less often measured analytes, in addition to those mentioned here, as well as physical and microscopic analysis of seminal fluid; glucose and protein determinations in synovial fluid; and protein, various enzymes and pH in transudates and exudates of pleural, pericardial and peritoneal cavities.

7 WHERE WE ARE IN THE YEAR 2000

The chemical analysis of urine has attained an important role in the clinical laboratory, in the physician's office and in home testing by the patient. We have emphasized the more common analyses performed on urine by professional chemists, medical technologists and technicians in laboratory settings. But there are millions of tests performed on urine specimens by individuals. Among the most common are pregnancy tests. These are based on the same chemical principles as those used for laboratory testing. Fertility testing, and urine glucose and ketone monitoring by diabetics are other home tests often used. In addition, tests for UTIs are performed by patients who have recurring infections, and
